White stock mice, injected with 0.25 cc. of emulsion via a tail vein, were killed by decapitation at specified intervals. Blood collected in heparin during decapitation, and various tissue specimens taken immediately thereafter, were examined for radioactivity. The specific activity of each tissue,

³ Radioactivity in 1 cc. of urine, expressed in per cent of the activity circulating at zero time in 1 cc. of plasma.

Fig. 1

FIG. 2

in per cent of the activity circulating at zero time, was determined by a technique previously described (1, 22, 24). This experiment was performed in three groups of eight to 12 mice each.

The results of a representative distribution study (Figure 1), calculated according to methods reported elsewhere (22) are expressed in per cent of total activity injected. Errors in radioactivity determinations due to differences in dry weights of different tissues were not corrected, but the dry weight of the same tissue in different animals was remarkably uniform (22).

Following injection, the radioactivity disappeared rapidly from the blood. Three hours after injection, lung, liver, and spleen showed high levels of specific radioactivity, that of lung being extraordinarily high.

Twenty-four hours after injection, however, the level of radioactivity was highest in spleen, next highest in lung, and next in liver. The level in spleen increased thereafter, and continued at a high level for six to eight days, but that in liver and lung slowly declined. The specific activity in thyroid was high, but the cumulative increase with time, observed in the dog, did not occur. Intestine and fat showed a very low level of activity. Brain, muscle and skin showed no measurable activity.

In another group of some 20 male mice, similarly injected, specimens of urine and feces were collected at various intervals after injection and

measured for radioactivity. The urine specimens were obtained by aspiration of the exposed bladder of these mice, sacrificed ten to 24 hours following ligature obstruction of the penile urethra (22). This was done at varying intervals from zero to 140 hours after injection. The urine and feces were transferred to aluminum cups for evaporation to dryness and radioactivity determination (Figure 2). The radioactivity in urine, which was still considerable four to five days after injection (Figure 2), as already stated above for dogs, was presumably in the form of ionic iodine cleaved from the fat. The low activity in the feces may have been due to a small amount of labelled fat excreted into the intestine.

DISCUSSION

Other investigators (8-19) have studied the immediate distribution of intravenously injected, non-radioactive, iodized fat emulsion in dogs and rabbits by determining the total iodine content of various organs. The injected fat left the blood stream rapidly (10, 13) and was retained in part by the lungs (9, 18, 19) or by the liver (8, 11, 12, 14) depending on particle size. Nearly all of an emulsion of greater particle size was deposited in the lungs (14) while most of an emulsion of smaller particle size was deposited in the liver (8, 11, 12, 14) or in the spleen (10, 11). Blockade of the reticulo-endothelial system by colloidal

silver, according to one investigator, resulted in diversion of the fat to the lungs and the liver parenchyma (10), while in similar experiments by others (11) such blockade was said to have had no effect on the distribution of the injected fat, which was reported to be retained by the liver (11).

More reliable indication of the initial distribution of intravenously injected fat is provided by determining the radioactivity of tissues soon after injection of radioactive iodized fat. This is so because the liberation of iodine from the fat molecule is relatively slow, as indicated (1) by the fact that iodine, which appears in the urine as soon as it is liberated, is not found in the urine in any quantity until an hour after the injection of iodized fat, and (2) because the urine shows a continuously high level of radioactivity for five to six days after injection of the emulsion. The metabolic cleavage of iodine from the fat molecule therefore appears to take place gradually and continuously.

From our data, it is not possible to determine the rate of metabolism of the iodinated or deiodinated fat. But the data on specific activity of various tissues are interesting in respect to this question (Table III). The very high specific activity in liver, lung and spleen 24 hours after injection probably reflects the storage function of the reticulo-endothelial system for particulate matter. Comparison of these data from Dog 24 with those of Dog 21 suggest that the spleen and lungs continue to act as depots, steadily, though slowly, giving up their stores, while the liver loses its stores much more rapidly, either by catabolism or by delivery to fat depots. The latter destination of the fat before deiodination has occurred seems unlikely in view of the continuously negligible lack of specific activity of mesenteric fat in five successive experiments. One may hazard the inference that fat depots cannot store any but structurally normal fat or that fat for which there is current need does not participate in the metabolic activity of fat depots. The latter possibility is unlikely in view of Schoenheimer and Rittenberg's study of fat labelled with deuterium (25).

The excretion of radioactivity into the urine, beginning within one hour after injection, represents ionic iodine liberated continuously over a period of several days.

CONCLUSIONS

An emulsion of radioactive iodinated fat injected intravenously in dogs and mice leaves the circulation rapidly.

Approximately 60% of the radioactivity still present in the circulation 24 hours after injection is contained in the lipid fraction of the plasma and 20% in the ionic iodine fraction.

Immediately after injection, the highest concentration of radioactivity in the tissues of dogs is found in the spleen, lung and liver, in that order, and decreases slowly. In tissues of mice the concentration of radioactivity immediately after injection is highest in the lungs. There it drops rapidly, while the concentration of radioactivity in the spleen increases rapidly and remains high for six to eight days after injection.

Iodine is gradually and slowly liberated from the iodinated fat and excreted. Iodinated fat is not stored in mesenteric fat depots.

THE MEASUREMENT OF EXTRACELLULAR FLUID IN MAN BY MEANS OF A CONSTANT INFUSION TECHNIQUE¹

BY IRVING L. SCHWARTZ,² DAVID SCHACHTER, AND NORBERT FREINKEL

(From the Department of Physiology, New York University College of Medicine, New York City)

(Received for publication April 8, 1949)

The principle substances in use to date as indicators of the extracellular water volume do not fulfill the basic requirement of exclusive distribution in the extracellular space.

Sodium is normally present in erythrocytes (1-3), striated muscle (4, 5), spinal cord, cartilage and bone (4, 6, 7). Chloride penetrates erythrocytes, connective tissue, pyloric mucosa, testes, salivary glands and cells of the central nervous system (6, 8). Bromide interchanges freely with chloride in all tissues except the central nervous system (9, 10) and therefore probably shares with chloride the property of cell penetration. Thiocyanate is bound to lipid and penetrates erythrocytes, gastric mucosa and other tissues (7, 11-14) and in bacteremia, spotted fever and malaria, and following artificial hyperpyrexia thiocyanate space may approach the value for total body water (15-17). Apparently, therefore, these ions may be used in normal individuals only for approximation of the volume of extracellular water, and in pathological states altered cellular permeability may invalidate even such approximate measurements.

Inulin, sucrose and mannitol are distributed throughout a consistently lower fraction of body water than are the electrolytes (18-23). Although these substances appear to circumvent the problem of cell penetration, they raise the question of how may plasma-interstitial fluid equilibrium be assured in the face of rapid elimination, slow diffusion, or both?

Any substance distributed in some fixed fraction of the body water will approach a uniform or equilibrium concentration throughout that compartment under conditions where its rate of infusion (in milligrams per minute) and its clearance or specific rate of removal (in milligrams per min-

ute per unit plasma concentration) remain constant for a sufficiently long period of time. After uniform distribution is attained, if the infusion is stopped and the total amount of the substance present in the body water is recovered quantitatively in the urine, its volume of distribution is the amount recovered divided by the equilibrium plasma water concentration. The use of inulin in the constant infusion method in dog and man has been reported in a preliminary paper (23), and more definitive data are available in the dog (24). The studies described here were undertaken to supplement our preliminary observations and to develop a standard constant infusion method for the measurement of inulin space in man.

METHODS

Twenty-nine studies were carried out in ten normal male subjects ranging from 21 to 55 years of age, and in five elderly male patients with congestive heart failure³ ranging from 45 to 60 years of age. In six of these studies a single intravenous injection of 50 to 75 cc. of 10 per cent inulin was given from a syringe calibrated at 20° centigrade with mercury or water at arbitrary marks. For the next 24 hours samples of blood and serial urine collections were obtained.

In the remaining 24 studies a priming injection of inulin was followed by a constant sustaining infusion for 1.7 to 30 hours. Assuming a distribution volume of 18 per cent of body weight, the prime was calculated to yield a plasma concentration of 10 to 30 mg. per cent and the concentration of sustaining infusion was calculated on an assumed filtration rate. Inulin solutions were made up in sterile isotonic saline except those for the cardiac patients where 5 per cent dextrose in distilled water was used. Constancy of the infusion rate in the first five studies was maintained by adjusting a Murphy drip every five to ten minutes. In all other experiments this was achieved with a constant infusion pump. The rate of

¹ Aided by grants from the Commonwealth Fund and the U. S. Public Health Service.

² National Institutes of Health Postdoctorate Research Fellow.

³ The five patients with congestive heart failure were subjects who had been infused with inulin during the course of studies conducted by Dr. David Baldwin, Dr. Herman Villareal, and Dr. Jonas Sirota, who kindly allowed us to utilize these infusions in order to determine the inulin space.

infusion used was 1.3 cc. per minute in all normal subjects and 0.3 cc. per minute in the cardiac patients. Calibration of this pump in successive 15, 30 and 60 minute periods revealed variation of less than 1 per cent at the higher rate and less than 3 per cent at the lower rate.

Varying lengths of infusion were utilized in the same individual whenever possible in order to determine the minimal time for equilibration of plasma water and interstitial fluid and to observe the reproducibility of the measurement of inulin space.

No preparation of the subject was made other than an attempt to maintain adequate and uniform hydration with a urine flow of 2 to 4 cc. per minute during the infusion. Before the priming injection a control blood and timed urine sample were obtained for determination of plasma blank concentration, B_0 , and the rate of urinary excretion of inulinoid blank, U_0V , which quantities were subtracted respectively from subsequent plasma concentrations and from the total inulin excretion during the post-infusion recovery period. Two or more blood samples were taken during the infusions to ascertain constancy of the plasma concentration. Shortly before stopping the infusion, the bladder was catheterized and a final blood sample was drawn. The bladder was washed well with isotonic saline and air. At completion of the wash-out the infusion was discontinued and all subsequent urine was collected in 0.5 to six hour long periods for the next 22 to 48 hours. In the subjects used for repeated studies blood samples were drawn at periodic intervals during this post-infusion period so that the decrement in plasma concentration with time might be compared in the same individual following varying periods of infusion. Blood samples were drawn from an antecubital vein using 0.1 cc. Liquaemin (Hoffmann-La Roche) per 10 cc. of whole blood as an anticoagulant. The patients with congestive heart failure were given 2 cc. of mercupurin intravenously shortly after the infusion was discontinued.

Our present criterion for equilibrium distribution of inulin throughout the extracellular fluid is attainment of a maximal and constant volume of distribution as the duration of infusion is successively increased in the same individual.

In some subjects, thiocyanate, bromide and Na^{24} spaces were also determined by the single injection method. Blood samples were drawn after one hour for thiocyanate and after three to four hours for bromide and Na^{24} determinations. Thiocyanate was determined by the method of Crandall and Anderson (11) adapted to the Beckman Spectrophotometer, model DU. Readings were made at a wave length of 460 m μ using cuvettes with a light path of 10 mm. Bromide was determined by the method of Brodie and Friedman (25), inulin by Harrison's modification (26) of the method of Alving, Rubin and Miller (27), and Na^{24} was measured with a Geiger-Müller counter. The plasma concentrations of inulin, thiocyanate, bromide and sodium are corrected for a plasma water content of 94 per cent and the concentrations of thiocyanate, bromide, and Na^{24} are corrected for the Donnan factor k : for thiocyanate and bromide, $k = 1.05$ and for

Na^{24} , $k = 0.95$. No correction was made for plasma protein or lipid binding of thiocyanate.

Urines were yeasted and precipitated in the same manner as the plasma. In some cases urines were yeasted both before and after dilution to a U/P ratio of 1, in which case the determinations compared within 2 per cent. Analyses were checked frequently by recoveries of known amounts of inulin added to water and plasma. The pH of the plasma filtrate was kept at or below 7.

The rate of excretion of inulinoid blank, U_0V , was determined in 30 successive one to three hour urine periods for eight to 24 hours in four normal subjects at urine flows varying from 0.4 cc. per minute to 10 cc. per minute, both in the fasting state and during unrestricted dietary intake. Blank excretion showed no relation either to urine flow or time after eating. The average U_0V of 53 periods including the above, was 0.16 mg. per minute with a standard deviation of ± 0.055 mg. per minute. Inulin space errors due to variation in U_0V become less significant as the equilibrium plasma concentration is elevated. In a normal subject with a plasma concentration of 30 mg. per cent and an inulin space of 10 liters, the average error to be expected from variations in U_0V during a 15 hour recovery period is 1.7 per cent, and the error to be expected from complete neglect of U_0V is 4.8 per cent.

RESULTS

Equilibration Time. The inulin volume of distribution was not increased significantly when the infusion was extended beyond 4.5, 3.3, 3.8, 7.5 and seven hours in five normal subjects, respectively, as compared with a minimal infusion period of 1.7 hours (Table I). In one of these subjects determinations were made with infusion periods varying from 1.7 to 17.5 hours. Inulin space increased asymptotically with the duration of infusion approaching a limiting value of 13.7 liters, as calculated by a first order differential equation applied to a curve drawn through the observed points (Figure 1). In this subject the inulin space after five hours of infusion was 95 per cent of the limiting value. The curves of declining plasma concentrations following cessation of infusion at 4.5, 5.5 and 17.5 hours were virtually superimposable when plotted on the same scale (Figure 2). We conclude that for all practical purposes plasma-interstitial fluid equilibrium was established in this subject by five hours.

After a single intravenous injection of inulin the curve of plasma concentration plotted against time shows two phases: an early rapid decrement followed by a period of more gradual decrement.

FIG. 1. INULIN VOLUME OF DISTRIBUTION DETERMINED AFTER VARIOUS PERIODS OF INFUSION IN THE SAME INDIVIDUAL

FIG. 2. CONCENTRATION OF INULIN IN PLASMA FOLLOWING A SINGLE INJECTION AND INFUSIONS OF 4.5, 5.5 AND 17.5 HOURS

For the single injection the equilibrium plasma concentration was calculated as the amount of inulin injected divided by the inulin volume of distribution as determined previously by the infusion method.

TABLE I

Volume of distribution of inulin, thiocyanate, bromide and radioactive sodium in man

* No catheterization, bladder emptied by spontaneous voiding when infusion stopped.

† Patients with congestive heart failure: J. T., Rheumatic heart disease, ++ peripheral edema, enlarged tender liver, moist rales at both lung bases. F. C., Rheumatic heart disease, +++ peripheral edema, enlarged tender liver, right pleural effusion. T. N., Cor pulmonale, ++++ peripheral edema, advanced congestive heart failure. A. D., Arteriosclerotic heart disease, no peripheral edema, dyspneic, orthopneic, depressed breath sounds and moist rales at both lung bases. T. P., Arteriosclerotic heart disease, generalized anasarca on admission to the hospital, digitalized on the ward with good response, + edema on 11/3/48 when infusion stopped.

Two similar phases are seen in the falling curve observed after stopping a constant intravenous infusion, but the initial period of rapid decrement is less prolonged. The duration of this initial phase decreases progressively with increasing durations of infusion until a minimum is reached at equilibration time. Following longer periods of infusion, the curves are identical (Figure 2).

Estimation of equilibration time by serial determinations on the same individual was not feasible in patients with congestive heart failure.

In Patient F. C., who had extensive edema and a right pleural effusion, equilibrium between pleural fluid and plasma was not achieved 20 hours after starting the sustaining infusion. Simultaneous pleural fluid and plasma water inulin concentrations were 13.0 mg. per cent and 17.7 mg. per cent respectively.

Recovery of inulin in urine after single injection. When 5 to 7 gm. of inulin were injected into six normal subjects, urinary recovery accounted for 98.0, 97.6, 91.5, 94.4, 98.7, 101 per cent of the

amount injected. Over 95 per cent of the total amount recovered was excreted in nine hours (Table II).

Recovery time following infusion of inulin. In the normal subjects, analysis of the cumulative post-infusion recoveries shows that over 95 per cent of the ultimate total recovery was collected at the end of 12 hours, and over 98 per cent of the ultimate recovery was collected at the end of 15 hours (Figure 3). In the patients with edema of congestive failure the quantity of inulin recovered in 22 to 30 hours was 98 per cent of the ultimate total amount recovered in 48 to 72 hours.

Inulin volume of distribution. In the seven

normal subjects the inulin space ranged from 14 to 18 per cent of body weight, with an average of 16.2 per cent. No attempt was made to correlate inulin space with body surface area, but it was noted that higher values in terms of per cent of body weight were obtained in lean individuals. Precision of the measurement may be judged by the reproducibility of values in repeated determinations on the same individual. In the five subjects in whom long infusions (exceeding five hours) were repeated, the largest inulin space difference observed in successive measurements was 0.5 liters and the smallest difference was 0.1 liters.

Inulin space in five patients with congestive heart failure ranged from 18.5 to 39.4 per cent of body weight and correlated directly with the degree of edema, as judged clinically. These values, however, may still be low because of failure to attain equilibrium despite infusion for 26 to 30 hours.

Comparison with other methods. Simultaneous thiocyanate, bromide and Na^{24} spaces were all significantly higher than inulin space (Table I).

DISCUSSION

That inulin does not penetrate cells seems probable *a priori* because of its high molecular weight and elongate configuration (28, 29). It does not enter erythrocytes (30, 31), bile (21, 32), gastric juice (31, 32) or cells of the renal tubule (30, 33), and no enzymes are known to be present in man which are capable of hydrolyzing it (30, 33). It is neither metabolized nor stored in the body as evidenced by its rapid quantitative urinary excretion (Table II). Our six urinary recoveries of inulin are in accord with the observations of others (34-36).

Our present values for the volume of distribution of inulin average 16.2 per cent of body weight as compared with significantly higher values obtained for the volume of distribution of thiocyanate, bromide and Na^{24} . The volume of distribution of mannitol is estimated to be 16 per cent of body weight in man when allowance is made for the metabolism of this compound (20). It appears, therefore, that inulin and mannitol occupy some constant fraction of body water which is smaller than the fraction occupied by any of the electrolytes used for the measurement of extra-

FIG. 3. RATE OF URINARY RECOVERY OF INULIN FOLLOWING CESSATION OF INULIN INFUSION IN EIGHT NORMAL SUBJECTS

cellular fluid (4, 7-10, 12, 14, 37-40). This smaller fraction of the body water conforms better with the values to be predicted from recent total body water measurements in man (41, 42). For these reasons we believe that the volume of distribution of inulin better approximates the true volume of extracellular fluid than the thiocyanate, bromide, chloride or Na^{24} space.

A study of the transcapillary movement of inulin indicates that the time required to establish equilibrium between plasma and interstitial fluid might be reduced if a higher priming dose relative to the sustaining infusion were used. Berger, Farber and Earle (43) have pointed to the importance of adequately estimating the filtration rate, and have shown that only one to one and one-half hours are required to achieve constant plasma inulin levels in normal subjects. Our experience confirms this point. It appears, therefore, that

variations in plasma concentration falling within the analytic error are compatible with incomplete saturation of remote phases of the interstitial fluid.

Extracellular fluid expansion increases the time required to establish plasma-interstitial fluid equilibrium and the time required for recovery of inulin in the urine. This constitutes a serious limitation of the application of the measurement of inulin space in edematous states, especially where there are large accumulations of pleural or peritoneal fluid into which inulin must diffuse. In these cases a similar infusion technique utilizing more rapidly diffusible substances may prove to be more suitable.

Failure of equilibration between plasma and interstitial fluid may result from variation of the filtration rate, the extracellular fluid volume or the infusion rate. For example, in Subject D. S. a pyrogenic reaction accompanied by an elevated

filtration rate was encountered, and the calculated inulin space was higher by 1.4 liters than any other observation of this subject. Infusion of saline over long periods of time may alter the filtration rate or the extracellular fluid volume; therefore, 5 per cent dextrose in distilled water is a preferable diluent for inulin in prolonged infusions.

The presence of inulin in the renal tubules, collecting ducts, pelves and ureters at the moment of stopping the infusion results in an error which raises the calculated inulin volume of distribution. This dead space error varies in the same direction as the renal delay time and inversely with the rate of urine flow at the time of stopping the infusion; however, if urine leaves the renal pelves and ureters in intermittent spurts, an assumed relationship between the renal delay time and rate of urine flow may not afford a reliable correction of the inulin space in this method. The data presented here are not corrected for the renal dead space; but during the infusions in our normal subjects the urine flow was maintained at 2 to 4 cc. per minute in order to minimize this source of error. In patients with congestive failure, where the rate of urine flow is less than 1 cc. per minute, the renal dead space error may increase the calculated inulin space considerably. Direct measurement of the volume and concentration of the urine contained in the renal calyces, pelves and ureters of a dog accounted for 7.6 per cent of a previously determined inulin space. The rate of urine flow in this animal at the time the ureters and renal blood vessels were ligated was 0.8 cc. per minute (31).

The determination of inulin space in patients with edema and oliguria involves both the error from failure to effect equilibrium distribution of inulin and the error of the renal dead space. Although these errors tend to cancel each other to some degree, it is necessary in such cases to prove that plasma and interstitial fluid concentrations are the same by analysis of the edema fluid and to minimize the renal dead space error by instituting diuresis shortly before the infusion is stopped.

SUMMARY

1. In normal human subjects after a priming dose and a constant intravenous infusion of inulin:

- (a) A period of five hours is sufficient for essentially homogenous distribution of inulin throughout the volume of distribution.
- (b) A period of 12 to 15 hours is required for quantitative urinary recovery of the inulin present in the body after the infusion has been discontinued.

2. The volume of distribution of inulin, determined by dividing the total amount recovered in the urine after stopping the infusion by the concentration in plasma water at equilibrium, averages 16.2 per cent of body weight. This value is significantly lower than the volumes of distribution of thiocyanate, bromide and Na^{24} determined simultaneously with the inulin space or in successive experiments.

3. Inulin space is reproducible in the same individual with different durations of infusion in excess of the minimum infusion time required for equilibrium.

4. The calculated inulin volume of distribution in five patients with congestive heart failure ranged from 18.5 to 39.4 per cent of body weight and correlated qualitatively with the observed degree of edema.

5. Extensions and limitations of the constant infusion principle for the determination of extracellular fluid volume are discussed.

ACKNOWLEDGMENTS

We gratefully acknowledge the generous counsel of Dr. Domingo Gomez and the assistance of Dr. Ernest Breed and Miss Babette Solomon. We are indebted to Dr. Eugene Berger of the Third (New York University) Research Service, Goldwater Memorial Hospital, for the bromide analyses.

STUDIES OF THE ROLE OF THE LIVER IN HUMAN CARBOHYDRATE METABOLISM BY THE VENOUS CATHETER TECHNIC.

II. PATIENTS WITH DIABETIC KETOSIS, BEFORE AND AFTER THE ADMINISTRATION OF INSULIN^{1, 2}

By PHILIP K. BONDY, WALTER LYON BLOOM, VIRGINIA S. WHITNER
AND BETTY W. FARRAR

(From the Departments of Medicine and Biochemistry, Emory University School of Medicine, and Grady Memorial Hospital, Atlanta, Ga.)

(Received for publication April 4, 1949)

The recent development of methods for the estimation of the blood flow and metabolism of the liver in man has made it possible to investigate the role of this organ in the normal and deranged metabolic processes of the human being. Previous studies have been concerned with the role of the liver in the carbohydrate metabolism of the normal human being (1). Similar investigations of patients with decompensated diabetic ketosis are reported in the present paper.

METHODS

Hepatic venous blood was obtained by a catheter passed through the right antecubital vein into a right hepatic vein. Blood was drawn from a Cournand needle lying in the femoral artery. The hepatic blood flow was estimated by the bromsulfalein extraction method of Bradley *et al.* (2). The technics of analysis have been discussed previously (1). In addition to studies of glucose and urea, ketone bodies were determined by the method of Weichselbaum and Somogyi (3). Throughout this paper, ketone bodies are expressed as the sum of acetone plus acetoacetic acid plus beta-hydroxybutyric acid (*i.e.*, total ketone bodies). The standard errors of the various technics in our laboratory have been as follows: Glucose, ± 1.0 mg. per 100 ml. at a level of 100 mg./100 ml.; urea, ± 0.1 mg. per 100 ml. at a level of 30 mg./100 ml.; ketone bodies, ± 8.2 mg. per 100 ml. at a level of 100 mg./100 ml.

After several pretreatment observation periods, insulin was injected intravenously. In one case, an infusion was given, at a rate of 1 unit per minute. All other patients received 25 or 50 units every 30 minutes. All insulin used was Lilly "regular" insulin. Samples were collected simultaneously from the femoral artery and the hepatic vein at 15 minute intervals. No glucose was adminis-

tered during the test. All patients had been fasting for at least 18 hours before the beginning of the observations. An accurate voided urine was collected for the 180 minute period of the experiment, and analyzed for glucose and ketone bodies.

CLINICAL MATERIAL

Five patients with diabetes mellitus were studied. These patients had been well controlled on insulin and a diet containing more than 150 grams of carbohydrate prior to the study, but had received no insulin for periods of 36 to 72 hours before the investigation was begun. No disease other than diabetes was evident, and none of the subjects were obese. Urine tests for ketone bodies were positive in all patients at the time the observations were started.

CALCULATIONS

The arterio-hepatic venous difference (A-HV) was obtained by subtracting the hepatic venous concentration from the arterial concentration. A positive value for this difference indicates that the splanchnic system was retaining the substance in question. By multiplying A-HV by the estimated hepatic blood flow (EHBF), the total splanchnic balance could be obtained. The relationship of this value to the hepatic balance is discussed below.

In the case of the ketone bodies, the large standard error of the method made it impossible to determine the value of A-HV with confidence in a single observation. The mean value of A-HV for the entire period was estimated by plotting graphically the arterial and hepatic venous concentrations against time, and integrating the difference with a polar planimeter. It was thus possible to obtain the mean difference of several estimations.

The rate of formation of glucose precursors from protein was estimated from the rate of urea production, assuming that the synthesis of 1 gram of urea releases 1.4 grams of glucose. The justification for this assumption has been discussed previously (1).

The rate of peripheral utilization of glucose and ketone bodies was calculated by subtracting the urinary excretion from the hepatic output. The caloric equivalents of these substances have been estimated by multiplying the value for glucose by 4.0 and for ketone bodies by 5.0 calories per gram. This has been compared with the

¹ Presented at the meeting of the American Society for Clinical Investigation, May 3, 1948, Atlantic City, New Jersey.

² Part of the data presented in this paper have previously been published in abstract form (J. Clin. Invest., 1948, 27, 526).

"normal" basal metabolic requirement obtained from the tables of Aub and DuBois.

RESULTS

Hepatic blood flow: The mean hepatic blood flow appeared to be slightly higher than normal (Table I); however the difference was not significant chiefly because of the wide scatter of the values in the diabetic patients. Inspection of the table, however, indicates that the estimated hepatic blood flow varies directly with the total arterial ketone level. The correlation coefficient of this relationship is 0.86, and the value of p^3 less than 0.01. There was no significant relationship between the hepatic blood flow and the carbon dioxide combining power (Figure 1).

Hepatic glucose output in diabetic ketosis: The mean rate of glucose release by the splanchnic system in this group of patients was 6.9 ± 1.73 mg./kg./min. (Table I). This may be compared

³ P from Fisher's tables. A significant value is considered to be one less than 0.02. All calculations were based on the technics for evaluation of small samples.

FIG. 1. RELATIONSHIP OF HEPATIC BLOOD FLOW TO ARTERIAL KETONE BODY CONCENTRATION (LEFT) AND CARBON DIOXIDE COMBINING POWER (RIGHT)

with the value of 3.4 ± 0.7 mg./kg./min. in a group of normal individuals (1). The difference is significant (P less than 0.02).

It was possible to calculate the amount of glucose lost in the urine of three of the patients. In Table I it may be seen that in all cases the hepatic

† Total hepatic output, less loss in urine. This is equivalent to peripheral utilization.

output was sufficient to account for the entire urinary glucose loss, and also to supply from 42% to 77% of the normal basal energy requirement.

Urea production in diabetic ketosis: The rate of formation of urea in the five diabetic patients averaged $1.35 \pm .55$ mg./kg./min. as compared with 0.21 ± 0.05 mg./kg./min. in the normal human being (1), a significant difference.

The increased rate of urea formation reflects an increased rate of protein catabolism, which contributes to the glucose produced by the liver. The calculated amount of glucose produced from protein in the diabetics ranged from 8.2% to 42% of the total hepatic glucose output, with a mean of $21.2 \pm 6.4\%$. In normal fasting human beings, the mean conversion percentage was $7.3 \pm 1.0\%$

(1). The difference is significant. No relationship could be established between the rate of protein breakdown and the hepatic blood flow, the arterial ketone body level, the arterial glucose level or the carbon dioxide combining power.

Hepatic ketone body production in diabetic ketosis: The output of ketone bodies by the splanchnic system varied from 0.12 to 4.0 mg./kg./min. After subtracting the urinary ketone body loss, these substances were found to supply a caloric equivalent to the peripheral tissues of from 2% to 118% of the calculated total basal metabolic requirement (Table I).

The effect of insulin on the carbohydrate metabolism in diabetic ketosis: The protocols of the five patients during treatment are shown in Table

* After this observation, a clysis of insulin, 1 unit/minute, was given intravenously.

† After this observation, 50 units of insulin were given intravenously.

‡ After this observation, 25 units of insulin were given intravenously.

§ At this time, the patient received 50 ml. of water by mouth.

II. Within 15 minutes after the first injection of insulin a decrease in the arterial glucose level occurred. The decline was maintained throughout the entire treatment period, except in the case of J. W., after 45 minutes, and W. B., after 75 minutes. In the latter case, no insulin had been administered for 45 minutes when the arterial concentration of glucose levelled off.

In all cases except one, the splanchnic glucose balance remained negative, *i.e.*, the liver continued to pour out glucose into the circulation, until at least 45 minutes after the beginning of therapy. In the case of J. W. C., a temporary positive balance was established at 30 minutes. This patient had very mild ketosis, shown by a total arterial ketone body level of only 27 mg./100 ml.

In two cases (W. B. and J. W.), there was a temporary increase in the rate of glucose production shortly after the institution of insulin therapy.

The effect of insulin on the ketone body metabolism in diabetic ketosis: The ketone body level in the blood fell during treatment with insulin. The inaccuracies of the analytical method used make it impossible to ascertain the role played by the liver in this decline.

The effect of insulin on the urea metabolism in diabetic ketosis: Before treatment, all patients had negative values for A-HV, indicating that the splanchnic system was adding urea to the blood. In each instance, as treatment progressed, at least one observation was made in which A-HV was

positive (Table III). It was not possible to correlate this occurrence with the status of the glucose balance, although in two patients, the urea and glucose balance patterns were nearly parallel (J. L. G. and J. P.). The significance of this apparent retention of urea by the splanchnic system is discussed below.

DISCUSSION

The hepatic venous catheter technic permits one to estimate the metabolism of the entire splanchnic system. Since it is impossible at present to obtain portal blood from the intact human subject, it is not feasible to separate the activity of the liver from that of the extra-hepatic splanchnic organs. It is possible, however, to predict in some degree the direction and magnitude of the error which is introduced if one assumes that the splanchnic metabolism is equivalent to that of the liver.

It has previously been shown (1) that in the normal human subject, the error introduced by lack of data pertaining to portal glucose concentration is small under basal conditions. Because of the utilization of part of the glucose traversing the digestive organs and the spleen, there is a tendency to minimize the apparent amount of glucose contributed to the circulation by the liver. In the diabetic individual, however, the uptake of glucose by most tissues is reduced (4). This would decrease the magnitude of the error. In diabetic dogs, for example, the portal venous glucose concentration has been observed to be 3 mg./100 ml.

lower than the arterial, at an arterial concentration of 336 mg./100 ml. (5). This small difference could not be observed by the methods used for the present study. For the uncontrolled diabetic patient, therefore, splanchnic and hepatic glucose balances are probably essentially the same.

After increasing the utilization of glucose, by the administration of insulin, the hepatic and splanchnic balances can no longer be considered equivalent. As in the case of the normal subject, however, the error will always tend to minimize the glucose contribution of the liver. No data are available from which the magnitude of this effect can be estimated. The terms "splanchnic" and "hepatic" may therefore be used interchangeably in speaking of the glucose metabolism of the untreated diabetic, but the results of observations by the liver catheter technic after the administration of insulin must be considered only as reflections of the glucose metabolism of the entire splanchnic system.

The extra-hepatic splanchnic organs neither utilize nor produce urea. It is, however, impossible to estimate the amounts of urea which may be withdrawn from the blood and released into the intestinal tract in the bile, gastric, pancreatic and intestinal juices. This loss of urea into the gut may explain the apparent retention of urea by the splanchnic system in the treated diabetic patient. It should be noted, however, that the digestive juices contain urea in a concentration approximating that of the blood (6). The secretion of these juices would not, therefore, be expected to alter the concentration of urea in the blood traversing the splanchnic system.

The apparent splanchnic urea balance might also be altered by dilution of the blood passing through the gut, either by absorption of ingested water or by release of water formed by the oxidation of hydrogen-containing foodstuffs. The first source was eliminated by examining the patients in a post-absorptive state. In one instance, a patient received a drink of water by mistake during the procedure. A definite depression of the hepatic venous urea level occurred in the next specimen (Table III, W. B., 60 minutes).

Water of oxidation is not sufficient to produce a perceptible alteration of hepatic venous concentration. The splanchnic oxidation of 180 mg. of glucose per minute (0.72 calories, equivalent to

about one-half of the basal metabolic requirement) would reduce the hepatic venous urea concentration by only about 0.1 mg./100 ml., a difference within the error of the method of determination.

Although the quantitative relationships between the splanchnic balance and the hepatic balance of the substances studied is somewhat complicated, it should be emphasized that the chief cause of the alterations observed in the splanchnic balance is the activity of the liver.

The large error of the method for determining ketone bodies prevented the estimation of the small A-HV differences directly, and therefore no attempt was made to draw conclusions about the hepatic or splanchnic balances in short observations in the present study. Considerable conservatism should be exercised even with regard to the estimation of A-HV by planimetric methods. The results obtained in this manner are probably of the right order of magnitude, but cannot be considered as reliable as the glucose or urea determinations.

In spite of the small number of observations, a significant direct correlation has been found between the hepatic blood flow and the arterial ketone body level. It is not possible to determine whether the elevated ketone body concentration causes the increased blood flow, or whether both reflect some more basic derangement. This observation is consistent with the findings of Howarth, McMichael and Sharpey-Schafer (7) that in severe diabetic acidosis the cardiac output is normal or increased, and the peripheral vascular resistance is diminished. It is possible that the enhanced hepatic blood flow merely reflects the reduced vascular resistance of the extra-hepatic components of the splanchnic system. In view of the increased liver oxygen requirement for carrying on deamination and ketone body formation, however, it seems probable that the augmented hepatic blood flow is of importance in supplying oxygen needed for the pathologic metabolic activities.

The small number of observations probably accounts for the fact that the correlation between hepatic blood flow and the carbon dioxide combining power was not significant.

Calculation of the glucose balance showed a higher rate of release from the liver of the untreated diabetic patient than the normal human being. This finding is somewhat more definite

than the findings of Crandall and Lipscomb (8) in dogs. These authors found that pancreatectomized dogs released more glucose from their livers than did normal dogs, but the increase was not significant statistically. The apparent difference between the results in humans and dogs may be caused in part by the very high value of EHBV in patient J. P.

It has frequently been shown that the rate of peripheral glucose utilization is increased when the blood glucose level is raised (9). In spite of the high dextrose concentrations found in the diabetic patients, however, carbohydrate utilization was not increased as compared to normal subjects previously studied by the same technic (1). These data, therefore, indicate an increased hepatic glucose output and a relative under-utilization of carbohydrate in the decompensated human diabetic patient. It seems probable that the increased arterial glucose level, made possible in part by the high rate of glucose release by the liver, permits the diabetic tissues to utilize normal quantities of glucose.

It has been shown in diabetic human beings (10) and in animals made diabetic by pancreatectomy (11) or by alloxan (12) that the liver glycogen is usually decreased when the subjects are in severe ketosis. The increased glucose output could not, therefore, be explained merely on the basis of increased glycogenolysis. It can, however, be accounted for almost entirely by increased proteolysis. The finding of increased urea production and protein breakdown by the decompensated diabetic liver agrees with the findings of others by means of balance studies in man (13) and in animals (14). The increased formation of glucose accompanied by an increased rate of urea formation is consistent with Stetten's observations (15) that in alloxan-diabetic rats or rabbits there is a normal or increased rate of glycogen formation from substances smaller than hexose. In our patients, it appears that an increased availability of such glucose precursors occurred as a result of the deamination of amino acids in the liver. The resulting nitrogen-free fragments of amino acids appear to have been incorporated into carbohydrate and to account in large part for the increased glucose production.

Ketone bodies were also found to contribute to the metabolic pattern of the decompensated dia-

betic patient. As might have been anticipated, the percentage of the metabolic needs supplied by ketone bodies was proportional to the degree of ketosis.

The metabolic pattern presented in Table I is expressed in terms of percentage of normal basal metabolic rate supplied by glucose and by ketone bodies. In each case, except that of J. W. C., the mildest case, these percentages add up to more than 100%. This is probably chiefly because patients in diabetic ketosis are not in a basal condition. It should also be emphasized that the fact that a material is being retained by the tissues does not necessarily mean that it is immediately being used for the production of energy. It is not possible by the technics used to estimate the importance of substances previously stored as fat, muscle glycogen, etc., in supplying the metabolic requirements of the organism. Moreover, the actual metabolic rate was not determined in these patients at the time of observation. The percentages presented, therefore, do not reflect the portion of the actual metabolic needs supplied by each of the components.

Presumably, the glucose retention following the injection of insulin reflects the formation of glycogen by the liver, although an enhanced formation of fat in the liver and viscera probably also takes place. The effect of the extra-hepatic viscera, as mentioned above, is to cause an apparent increase in the retention of glucose by the splanchnic system. The delay in the retention of glucose by the splanchnic viscera is therefore shortened by the effect of the activity of the extra-hepatic splanchnic system. The apparent delay of one hour before glucose was retained by the splanchnic system therefore implies that an even longer time was necessary before the liver began to retain glucose. Direct observations of the liver glycogen of diabetic patients (10) have shown that after treatment with insulin the glycogen concentration increases slowly at first and accelerates as therapy proceeds. This is consistent with the observations in the present series of patients.

In two patients, there was actually a considerable increase in the rate of release of glucose by the liver after the administration of insulin. The presence of glycogenolytic substances in commercial insulin has recently been emphasized (16). The

effect noted in these patients may have been due to the presence of this material in the insulin.

After the administration of insulin, there was a decrease in the rate of urea formation until all patients, at one time or another, had a positive splanchnic balance. As discussed above, some part of this retention of urea may have been artifact. In certain instances, however, the retention was of such magnitude that this effect seems insufficient to account for them (Table III, J. L. G., 45, 60, and 75 minutes; J. W., 45, 60, 75 minutes; J. P., 90 minutes). One is therefore tempted to consider the possibility that urea may have re-entered the body economy of these patients. Schoenheimer (17) has shown that in normal fed rats 96% of orally administered nitrogen-labeled urea is recovered unchanged in the urine. Leifer *et al.* (18), however, have shown that up to 20% of the radioactivity of injected carbon-labeled urea may be recovered in the expired carbon dioxide within three hours. Certainly the period of recovery from diabetic acidosis should be one of the best times to see any anabolic activity of urea which is perceptible by ordinary chemical methods of study. The effect of insulin on protein metabolism, in any case, appears to be dramatic. The inhibition of hepatic urea formation occurs so early that it preceded or paralleled the carbohydrate effects in all cases. J. L. G., for example, had a positive splanchnic urea balance after 45 minutes of treatment, but did not begin to retain glucose even after 75 minutes.

SUMMARY

Five patients with uncontrolled diabetes mellitus have been studied by the liver catheterization technic. There was an increased rate of splanchnic glucose and urea production as compared with normal subjects. As the arterial ketone body concentration rose, the hepatic blood flow also increased. There was a normal rate of utilization of glucose in the peripheral tissues. Ketone bodies were also utilized.

After the administration of insulin, the arterial glucose level fell and the rate of splanchnic glucose production decreased. After latent periods of from 45 to more than 75 minutes, the splanchnic system began to retain glucose, presumably chiefly as glycogen. In two instances, there was a considerable temporary increase in hepatic glu-

cose production immediately after the injection of insulin. This may have been due to the effect of the insulin glycogenolytic factor.

The rate of urea production was rapidly reduced by insulin. In all instances, the splanchnic system retained urea for one or more experimental periods while under the influence of insulin. This effect occurred at least as rapidly as the effects on carbohydrate metabolism.

STUDIES OF THE PULMONARY CIRCULATION. I. THE CIRCULATION TIME FROM THE PULMONARY ARTERY TO THE FEMORAL ARTERY AND THE QUANTITY OF BLOOD IN THE LUNGS IN NORMAL INDIVIDUALS^{1, 2}

By RICHARD V. EBERT, CRAIG W. BORDEN, HERBERT S. WELLS,
AND RUSSELL H. WILSON

(From the Department of Medicine, University of Minnesota, and the Veterans Administration Hospital, Minneapolis, Minn.)

(Received for publication February 21, 1949)

The measurement of the volume of blood contained within the vessels of the lungs has excited considerable interest for many years. A direct method of measurement by clamping the pulmonary vessels, removing the lungs and determining the amount of hemoglobin contained therein has been used on laboratory animals (1). A method that is applicable to intact animals and to human beings was developed by Stewart (2), using the formula $Q = \frac{TV}{60}$, where V represents the minute volume of the heart, Q the volume of the blood in the lungs and T the mean pulmonary circulation time in seconds. By measuring V and T , Stewart found that the average pulmonary blood volume (Q) in a group of dogs amounted to 16 per cent of the total blood volume.

Blumbart and Weiss (3) determined the pulmonary circulation time in normal human subjects using an active deposit of radium. The material was injected into an antecubital vein of one arm and the time of arrival in the right heart and the brachial artery was noted. The term "crude pulmonary circulation time" was used to refer to the difference between the time of arrival of the radium in the right heart on the one hand, and the time of its arrival in the brachial artery on the other. From the "crude pulmonary circulation time" and the cardiac output the pulmonary blood volume was estimated.

The assumption was made both by Stewart (2)

¹ Published with permission of the Chief Medical Director, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

² Presented in part at a meeting of The American Society for Clinical Investigation in Atlantic City, N. J., May 3, 1948.

and by Blumgart and Weiss (4) that the most rapid circulation time does not differ significantly from the mean circulation time. Hamilton, Moore, Kinsman, and Spurling (5) measured the dye concentration in serial samples of blood obtained from the femoral artery immediately after the injection of a dye into a peripheral vein. When the concentration of dye in each sample was plotted against the time of collection of the sample, a characteristic curve was obtained which demonstrated that the mean circulation time differs considerably from the most rapid circulation time. By studies on artificial models they also validated Stewart's method for determining pulmonary blood volume. In addition, they developed a method of estimating the cardiac output from the concentration curve of the dye. By determining the mean circulation time (from a peripheral vein to the femoral artery) and the cardiac output, the volume of blood between the points of introduction and removal of dye was calculated from Stewart's formula.

The rate of peripheral venous flow is variable (3) and introduces considerable inaccuracy in the estimation of pulmonary blood volume by the method of Hamilton *et al.* (5). The direct injection of dye into the pulmonary artery through a catheter obviates this difficulty by eliminating the circulation time from the peripheral vein to the pulmonary artery. Catheterization of the pulmonary artery also permits accurate determination of the cardiac output (6, 7).

METHOD

Thirteen normal fasting male adults between the ages of 30 and 40 were studied. One was eliminated from the series because of the development of marked anxiety during the procedure resulting in an extremely high car-

diac output. The subjects were either physicians or laboratory workers. A No. 8F or No. 9F catheter was introduced into the pulmonary artery by the method of Courmand, and a No. 18 needle with stylet was inserted into the femoral artery (8). The oxygen consumption was measured with a closed circuit spirometer and samples were drawn from the pulmonary artery and femoral artery for the determination of oxygen content by the method of Van Slyke and Neill (9). Immediately thereafter, 5 cc. of a solution of the dye T-1824 containing 300 mg. of dye per 100 cc. were introduced as rapidly as possible through the catheter into the pulmonary artery, the average time required for the injection of the dye being 0.8 seconds. Time intervals were recorded on a direct writing electric kymograph by an assistant. In order to permit more accurate timing of the initial appearance of the dye in the circulation, 1 cc. of the dye was introduced into the catheter before beginning the injection.⁵ Consecutive samples of blood were collected.

For the determination of the dye curve, the serum was separated and 0.1 cc. was diluted with 2 cc. of saline solution. The dye concentration was then determined in the Evelyn photoelectric micro-colorimeter using a con-

⁵ The No. 9F catheter contains a volume of about 1.8 cc. from the femoral artery in small glass tubes which were arranged in series in a wooden rack. The blood spurting from the needle was allowed to flow directly into the sampling tubes. The average time required for collection of a sample was 1.9 seconds, each tube receiving 0.3 to 0.5 cc. of blood. After completion of the sampling from the femoral artery, the dye remaining in the catheter was washed into the circulation and a sample of blood was taken 10 minutes later. The plasma volume was determined from the concentration of dye in the plasma (10), and the total blood volume from the plasma volume and hematocrit reading.

trol sample of serum similarly diluted with saline as a blank.

To determine the mean circulation time, the concentration of dye in each sample was plotted against the time of collection of the sample on linear graph paper. The time of each sample was determined by measuring the interval between the mean time of the injection of the dye and the mean time of the collection of the sample. After the curve was plotted, the area subtended by the primary dye curve was measured with a planimeter. The vertical line that divides this area into two equal parts represents the mean circulation time.

The cardiac output was calculated by the Fick principle (6). The quantity of blood contained in the pulmonary vessels, left heart, aorta and certain larger arteries (Q) is equal to the

$$\frac{\text{cardiac output (cc./min.)} \times \text{mean circulation time (sec.)}}{60}$$

according to the formula of Stewart (2).

RESULTS

The results are given in Table I, and a typical dye curve is illustrated in Figure 1. In all the experiments, the concentration of the dye in the blood obtained from the femoral artery was at or near zero before recirculation began. In those cases in which recirculation began before the primary curve was completed, the curve was extended to the base line for purposes of calculation (Figure 2). The average circulation time in the 12 subjects was 10.2 seconds with a standard deviation of ± 1.6 , and the average duration of the primary curve was 12.3 ± 2.4 seconds.

* Omitted in the calculation of mean values because the subject showed evidence of marked anxiety during the procedure.

FIG. 1. DYE CONCENTRATION CURVE IN NORMAL SUBJECT

The dye concentration reached zero before recirculation began. The mean circulation time is represented by the broken vertical line.

The cardiac output for the group was 6.92 ± 1.5 , and the cardiac index was 3.59 ± 0.72 liters per minute. The mean value for Q , calculated from Stewart's formula, was 1160 ± 246 cc. Correcting the individual values for Q to 1.73 sq. m. of body surface, gave a mean value for the group of 1045 ± 200 cc. Expressed as per cent of total blood volume, the mean for the group was 19.5.

DISCUSSION

As emphasized by Hamilton (5), the mean circulation time differs from the most rapid circulation time. The primary dye curve from which the mean circulation time is calculated is produced by dye particles travelling from the pul-

monary artery to the femoral artery at different rates of speed. In the study by Blumgart and Weiss (4), the most rapid circulation time rather than the mean circulation time was determined. If the apparatus for detecting the arrival of the radium in the brachial artery were extremely sensitive, the most rapid circulation time would differ considerably from the mean circulation time. If, however, the time recorded really represents the peak concentration of the substance, the value should correspond closely to the mean circulation time. As can be seen in Figure 1, the mean circulation time differs little from the time required to attain the maximum concentration of dye in the normal subject. It is of interest that the circula-

FIG. 2. DYE CONCENTRATION CURVE IN NORMAL SUBJECT

The dye concentration did not reach zero before recirculation began. The mean circulation time is represented by the broken vertical line.

tion time from the right auricle to the brachial artery, as measured by Blumgart and Weiss (3), is quite similar to the circulation time from the pulmonary artery to the femoral artery, as measured by the dye method, the average value for the former being 10.8 seconds and for the latter 10.2 seconds.

The value for Q , calculated from the formula of Stewart, represents the amount of blood contained within the pulmonary vessels, left heart, and certain of the larger arteries. Hamilton (5) has pointed out that on the systemic side of the circulation, Q includes the blood in the aorta and iliac arteries together with all the blood contained within the other branches of the aorta to points where dye arrives no later than it does at the femoral artery. It is apparent that in the pulmonary vessels, Q includes only blood which is circulating.

In comparing the value of Q in the present study with that obtained by Hamilton, it should be pointed out that in his experiments, the dye was injected into an arm vein. Thus, the mean circulation time included the time required for the dye to travel from the arm to the pulmonary artery in addition to the time of passage from the pulmonary artery to the femoral artery. Blumgart and Weiss (3) found that the circulation time from the antecubital space of the arm to the right heart was 6.7 seconds. This fact explains the considerably higher value for Q obtained by Hamilton and colleagues in normal subjects (5). The value for Q in their studies was 2 liters as compared with 1.16 liters in the present experiment.

In order to determine the true pulmonary blood volume, it is necessary to know the mean circulation time from the pulmonary artery to the left auricle, a value which was not determined in the present experiments. From the studies available in the literature it is difficult to estimate the true pulmonary circulation time. Nevertheless, it is apparent that the true pulmonary blood volume is less than the value for Q . A more accurate estimation of the true pulmonary blood volume must await a method for determining the mean circulation time from the pulmonary artery to the left auricle.

SUMMARY

1. The mean circulation time from the pulmonary artery to the femoral artery was determined by injecting the dye T-1824 into the pulmonary

artery and measuring the concentration of the dye in consecutive samples of blood obtained from the femoral artery. The mean circulation time in 12 normal subjects was 10.2 ± 1.6 seconds.

2. The volume of blood contained in the pulmonary vessels, left heart, aorta, and certain of the larger systemic arteries was calculated from Stewart's formula using the mean circulation time and the cardiac output as measured by the direct Fick method. The mean volume for the group of 12 normal subjects was 1160 ± 246 cc., or 19.5 per cent of the total blood volume.

(From the Department of Medicine, University of Minnesota, and the Veterans Administration Hospital, Minneapolis, Minn.)

(Received for publication February 21, 1949)

The pathogenesis of dyspnea in left ventricular failure and in mitral stenosis is not entirely understood but it is generally conceded that pulmonary vascular congestion is involved (1). Preceding the congestion there is probably an elevation in the left auricular and pulmonary venous pressures but to date it has not been possible to measure such pressures in the human being. Accurate quantitation of the pulmonary vascular congestion itself is difficult and the use of the vital capacity for this purpose is far from satisfactory. Much more promising in this connection is a method, described in a previous paper (2), which measures the volume of blood in the lungs, left heart, aorta, and certain systemic arteries. The method is based on the measurement of the mean circulation time from the pulmonary artery to the femoral artery, and the simultaneous determination of the cardiac output. An increased volume of blood in the pulmonary vessels should result in a corresponding increase in the total volume of blood (Q) measured by the technique. The results of studies based on this premise are presented in the following account.

MATERIAL AND METHODS

A group of 10 men with rheumatic heart disease and mitral stenosis were studied. All these patients had dyspnea on exertion and some degree of pulmonary hypertension. As examples of left ventricular failure, 18

men with disease of the aortic valve or hypertensive heart disease were chosen. All had dyspnea on exertion and had suffered from several episodes of paroxysmal dyspnea in the past, but none were severely orthopneic at the time the study was performed. Two of the patients with rheumatic heart disease and two with left ventricular failure previously had evidence of right ventricular failure manifested by hepatomegaly, peripheral edema and an elevated systemic venous pressure.

A catheter was introduced into the pulmonary artery by the method of Cournand and co-workers (3). The mean circulation time from the pulmonary artery to the femoral artery was measured and the cardiac output was determined as previously described (2). The volume of blood in the pulmonary vessels, left heart, aorta, and iliac arteries, together with all the blood contained within the other branches of the aorta to points where dye arrives no later than it does at the femoral artery (Q) was determined from Stewart's formula (4). The pressures in the pulmonary artery, right ventricle, and right auricle were measured with a Hamilton manometer. The level of the right auricle was determined by the method of Lyons, Kennedy, and Burwell (5). The pulmonary arterial diastolic pressure was measured immediately before auricular systole to avoid artifacts which occur in the pulmonary arterial tracing during auricular systole. The systolic pressure was determined from the right ventricular tracing, since artifacts due to motion of the catheter interfered with this measurement in the pulmonary arterial tracings.

Heart volumes were determined from the teleroentgenogram by the method of Keys *et al.* (6). The predicted normal frontal area of the heart for the individual was estimated from the nomogram of Ungerleider and Gubner (7). The predicted heart volume was obtained by the use of the tables of Keys *et al.* (6).

The vital capacity was measured in the sitting position with a spirometer. The predicted normal figure for the individual was obtained by applying the formula of Baldwin, Cournand, and Richards (8). Four and four-tenths per cent were added to the value obtained by this formula to correct for the difference between the supine and sitting position (9).

RESULTS

In order to determine the significance of the findings in the patients with heart disease it was necessary to compare them with the findings previously obtained in a group of 12 normal subjects (2). The dye concentration curves in patients with heart disease differed in most instances from the normal curve in that they were more prolonged than the normal and the maximal dye concentration was lower in the former than in the latter (Figure 1). Because recirculation usually began before the completion of the primary curve, a small error may have occurred in the determination of the mean circulation time. The mean circulation time was prolonged in the group with mitral disease and in the group with left ventricular failure, the increase being greater in the latter group (Table I). The mean cardiac index was significantly reduced in both groups as compared with the normal subjects.

The mean value for Q in 10 patients with mitral stenosis was 1230 cc. as compared with 1160 cc. in the group of 12 normal subjects ([2] Table I). This difference is not significant statistically. Adjusting the individual values to 1.73 sq. m. body surface resulted in a larger difference between the two means but the statistical significance of the difference remained doubtful.

The mean value for Q in the group of 18 patients with left ventricular failure was 1750 cc. which is

FIG. 2. CHART SHOWING CORRELATION BETWEEN HEART VOLUME AND Q IN PATIENTS WITH LEFT VENTRICULAR FAILURE

TABLE III

Comparison of mean increase in Q with mean increase in volume of the heart in 18 patients with left ventricular failure

	Left ventricular failure	Predicted normal	Mean increase
Volume of heart (cc.) Estimated from teleroentgenogram	1251	675	576
Q (cc.)	1750	1160	590

significantly greater than the mean value for Q in normal subjects (Table II). It was immediately apparent that the increase in Q in the group with left ventricular failure could be due to an increase in volume of blood in the left ventricle. In order to evaluate this possibility, the volume of the heart in the individual cases was plotted against Q (Figure 2). There was a moderate correlation ($r = 0.6954$ $p < .01$). In Table III the difference between the mean volume of the heart in the group with left ventricular failure and the predicted mean normal heart volume for the group is compared with the difference between the mean value for Q in the group with left ventricular failure and the mean value for Q in the group of normal subjects. The two values were very similar.

The pulmonary arterial pressure was moderately elevated in the group with left ventricular failure and more strikingly elevated in the group with mitral stenosis (Tables I and II). There was no correlation between Q and the vital capacity in either group.

DISCUSSION

The prolongation of the circulation time from a peripheral vein to an artery in heart disease is well known and is widely used in the clinical assay of congestive heart failure. In most studies of the circulation time, a method is used which gives a single end point. The means of detecting the end point differs, both in technique and in sensitivity, from method to method. For example, in the determination of the circulation time by the use of radium as performed by Blumgart and Weiss (10), the end point depends on the sensitivity of the detecting device and the concentration of the radium in the blood flowing through the brachial artery. Hamilton *et al.* (11) have demonstrated that this end point does not represent the mean

circulation time but merely approximates the earliest circulation time. A study of the dye concentration curve determined in patients with heart disease, makes it apparent that the measurement of the circulation time by the usual method will give a value which is quite remote from the true mean circulation time.

The importance of the determination of the mean circulation time lies in the fact that it is a function of the rate of blood flow and the volume of blood contained in a given portion of the circulation. According to Stewart (4) and Hamilton (11), the mean circulation time from the pulmonary artery to the left auricle should be inversely proportional to the cardiac output, and directly proportional to the volume of blood in the pulmonary vessels. Unfortunately, it is impossible to measure the circulation time from the pulmonary artery to the left auricle so that this approach to the estimation of the pulmonary blood volume is closed. It is possible, however, to measure the mean circulation time from the pulmonary artery to the femoral artery. Using Stewart's formula, one finds that this mean circulation time is inversely proportional to the cardiac output and directly proportional to the value Q , which represents the amount of circulating blood in the lungs, left heart, aorta, and certain other arteries as defined above. Hence, if the cardiac output and the mean circulation time are known, Q can be calculated. If the volume of blood in the aorta and left heart remains constant, variations in the pulmonary blood volume will cause corresponding variations in Q . Blood in the lungs which is stagnant or circulating very slowly would not be measured by this method.

There was no significant increase in Q in the group of patients with mitral stenosis and pulmonary hypertension as compared with the group of normal subjects, and it can be concluded, therefore, that there was no large increase in pulmonary blood volume. Moreover, a marked increase in pulmonary arterial pressure can occur in mitral stenosis without an increase in Q and, consequently, without a large increase in pulmonary blood volume. None of the patients studied had severe orthopnea or evidence of pulmonary congestion and edema roentgenologically. It is quite possible that a marked increase in pulmonary

blood volume does occur in patients with these findings.

There was a marked increase in Q in the group of patients with left ventricular failure. Gernandt and Nylin (12) have observed a relationship between increase in circulation time from peripheral vein to peripheral artery and increase in size of the heart. All patients with left ventricular failure in this study had varying degrees of left ventricular enlargement, and the largest increase in Q occurred in those patients with the largest hearts. A positive correlation existed between the heart volume and Q . If the mean increase in heart volume is compared with the mean increase in Q , the similarity of the two values suggests that they have a common cause, namely, an increase in the amount of blood in the left ventricle. In roentgenological studies of heart volume, it is impossible to distinguish between the effects of hypertrophy and dilatation but it is generally conceded that the increase in the size of the heart in heart failure is primarily due to cardiac dilatation (13, 14). Because of the contribution of the blood in the dilated left ventricle to Q , it is difficult to evaluate changes in pulmonary blood volume in patients with left ventricular failure.

The reduction in vital capacity in patients with heart disease has been attributed to pulmonary congestion with consequent changes in pulmonary distensibility and elasticity (15, 16). It has been suggested that prolongation of the circulation time in association with reduced vital capacity is due to an increase in the volume of blood in the lungs (17). From the present study, it does not appear that reduction of vital capacity is of necessity accompanied by a large increase in pulmonary blood volume, nor does it appear that an increase in pulmonary blood volume is the major factor in prolonging the circulation time.

SUMMARY AND CONCLUSIONS

1. The mean circulation time from the pulmonary artery to the femoral artery and cardiac output were determined on 10 patients with mitral stenosis associated with pulmonary hypertension and 18 patients with left ventricular failure.
2. From the mean circulation time and the cardiac output the volume of blood in the pulmo-

nary vessels, left heart, aorta and certain other arteries (Q) was calculated.

3. The mean circulation time was prolonged and the cardiac output was reduced in both groups as compared with normal subjects. The value for Q in the group of patients with mitral stenosis and pulmonary hypertension did not differ significantly from the value in normal subjects and hence, there was no evidence of a large increase in circulating blood in the lungs.

4. A marked increase in Q was present in the group of patients with left ventricular failure. Because of evidence which suggested that the increase in Q was largely due to an increase in the amount of blood in the left ventricle, it was impossible to evaluate changes in pulmonary blood volume in this group.

5. There was no correlation between the reduction in vital capacity and Q . This suggests that the reduction in vital capacity in patients with heart disease is not a direct function of increase in pulmonary blood volume.

MATURATION OF RENAL FUNCTION IN CHILDHOOD:^{1, 2} CLEARANCE STUDIES

By MITCHELL I. RUBIN, ERIKA BRUCK, AND MILTON RAPOPORT WITH THE
TECHNICAL ASSISTANCE OF MARJORIE SNIVELY, HELEN MCKAY
AND ALVERNA BAUMLER

(From the Department of Pediatrics, School of Medicine, University of Buffalo, and the Statler
Research Division of the Children's Hospital of Buffalo; and the Department of
Pediatrics, School of Medicine, University of Pennsylvania, and the
Children's Hospital of Philadelphia)

(Received for publication March 4, 1949)

Evidence has been presented by several investigators that functional capacity of the kidney in the premature and young infant is lower than in older children and adults. Schoenthal (1) using urea clearance, McCance and Young (2) urea and inulin clearances, Barnett (3) inulin clearance, and Gordon, Harrison and McNamara (4) urea clearance, showed that the infant had a lower glomerular function when compared to the adult on the basis of a unit of surface area. Recently West *et al.* (5) reported a study of renal function in infants during the first two years of life and Barnett *et al.* (6), a study in premature infants. This present study was begun in 1945 to determine the rate of maturation of certain of the kidney functions from the newborn period through childhood. The following functions were estimated: glomerular filtration rate, maximal tubular excretory capacity for para-amino-hippurate, urea clearance, and effective renal plasma flow.³ Sixty-three normal well children between the ages of two days and 12 years were studied.

METHODS

G.F. was determined as mannitol clearance by the single injection technique. A 20 minute period was allowed for

¹ Presented before the Society for Pediatric Research, Stockbridge, Mass., May 1947, and exhibited at the Fifth International Congress of Pediatrics, New York City, July 1947.

² The mannitol and para-amino-hippurate used in these studies were kindly furnished to us through the courtesy of Sharp & Dohme, Inc., Glenolden, Pennsylvania.

³ These abbreviations are used throughout the paper:

G.F. = glomerular filtration rate

P.F. = effective renal plasma flow

Tm_{PAH} = maximal tubular excretory capacity for para-amino-hippurate

F.F. = filtration fraction

PAH = para-amino-hippurate

equilibration before the first specimen was collected. The blood levels were plotted against time on semi-logarithmic paper; the blood level at the midpoint of each urine collection period, minus two minutes, read off the resulting curve. The mannitol levels in the blood when so plotted always formed a straight sloping line (a minimum of three and in the majority of instances four levels were determined). There was no evidence of lack of equilibration of mannitol in the body fluids after the period allowed. P.F. was determined simultaneously as the clearance of sodium para-amino-hippurate (PAH) at low plasma levels (between 0.5 and 3 mg. per 100 cc. of plasma); the tubular excretory capacity was determined by the excretion of PAH at high blood levels (between 50 and 100 mg. per 100 cc. of plasma). In several instances the Tm_{PAH} was calculated using the values for glomerular filtration rate determined in previous periods. In 27 instances where the Tm_{PAH} was determined simultaneously with the last period of mannitol clearance, the value for glomerular filtration rate was not influenced by the high concentration of plasma PAH. The blood level of PAH was maintained by a priming injection and a continuous intravenous infusion. The priming solution of PAH for Tm determination was always diluted in the syringe to three to four times its volume, either with the dilute solution remaining in the infusion tubing or with saline, and injected as slowly as possible. In larger children, where the volume might have been too large for a syringe, the priming solution was allowed to run in through the infusion tubing from an open burette flask. When injected rapidly and in concentrated form, this amount of PAH solution may cause a sensation of intense heat, involuntary defecation, nausea, vomiting, abdominal pain or pain in the extremity used for injection. With the technique just described, these reactions were usually mild or absent; with one exception they ceased shortly after completion of the priming injection. They seemed to be milder in infants than in older children. The test was started in the morning, after the child had had a light breakfast or, in the case of infants, a bottle one to three hours previously and was well hydrated.

The laboratory determinations of mannitol and PAH were carried out according to the methods outlined by Smith *et al.* (7, 8). Two modifications were used: (1) The deproteinization was performed by the Somogyi

method (one part plasma or, for mannitol, two parts yeasted plasma dilution, 10 parts distilled water, two parts 0.3 N barium hydroxide solution, two parts 5% zinc sulfate solution). (2) For the determination of mannitol the mixtures of plasma filtrate and acid periodate solution were left at room temperature overnight instead of being heated in a boiling water bath for 20 minutes prior to titration.⁴

The standard error of the mannitol clearance determination in a combined series of 75 tests with four periods each plus 60 tests with three periods each was 5.7 cc. with a mean error of 4.73 cc. \pm 0.49. The standard error of 103 determinations of renal plasma flow by PAH clearance with three periods each was 55.2 cc./min. with a mean error of 39.75 cc. \pm 6.44. The standard error of 112 determinations of the tubular excretory capacity for PAH, with three periods in each test, was 5.85 mg./min. with a mean error of 3.75 mg. \pm 0.55. These errors include both the laboratory determination and the bedside technique, such as urine collection, timing of specimens, etc.

The urea clearance was determined simultaneously with the mannitol clearance for three periods in each test.

⁴ Note: Incidentally this modification, which in our hands gave more constant results than the original method, may account for the fact that there is no evidence in our figures of the interference of high levels of PAH with the mannitol determination. Other investigators have recently reported such an interference (9).

Urea was determined in blood and urine with urease by the aeration method of Van Slyke and Cullen (10), but with boric acid substituted for the standard mineral acid in the receiving flask. Toward the end of this study, Conway's micro-method with urease, as modified by Steinitz (11), was substituted for the Van Slyke and Cullen method. Both methods give identical results.

It must be made clear that these tests were performed with a relatively high urine flow, resulting from the diuresis produced by mannitol and the intravenous infusion. This high urine flow does not alter the clearance rates greatly, with the exception of the urea clearance which may be somewhat higher than under ordinary conditions. Most of the tests were performed on quiet or sleeping children and, therefore, were presumably not unduly influenced by circulatory changes. Prolonged periods of starvation before performing the test were not deemed necessary. We found that the children were much quieter during the test if they were not hungry.

RESULTS

In Figure 1A we have graphically presented the glomerular filtration rates obtained at different ages throughout the first year. In Figure 1B the glomerular filtration rates of the children over one year of age are recorded in a similar fashion. Table I, column 11, gives the actual values for

FIG. 1A. GLOMERULAR FILTRATION RATE IN INFANTS

Each dot represents the average value in an individual child. The horizontal line represents the mean adult value of the glomerular filtration rate of an adult with a surface area of 1.73 sq.m. The broken lines represent one standard deviation from this mean, as determined in adults (12).

G.F. in cubic centimeters per minute and in column 10 the figures are corrected for surface area. The individual periods are listed in column 21 to show the variability from period to period. It is apparent from these data that the G.F. is very low in the very young infant, averaging about 50 cc./min. per 1.73 sq.m., and slowly rises during the first year, reaching adult values of about 130 cc./min. some time between the first and second year of life. Under six months of age none of the values were within the adult range when corrected for surface area and only a few in the last six months of the first year. In the second year many were found within the adult range, some still below. After the third year all values were found to be within the adult range.

Table I, column 14, shows the actual values obtained for P.F. in cubic centimeters per minute as measured by the clearance of PAH at low blood levels in the same group of infants and children, and column 13 gives the values per 1.73 sq.m. surface area. Figure 2A graphically presents the rate of effective renal plasma flow corrected to standard surface area as the child matures throughout the first year of life, and in Figure 2B the same

data are given for the older children. As in the case of G.F., the P.F. (corrected for surface area) is also low in the young infant, increasing gradually and reaching the average adult value around the second year.

Table I, column 17, lists the actual values obtained in estimating the maximal tubular excretory capacity in these children, and in column 16 the values are corrected for standard surface area. In Figure 3A the Tm_{PAH} in mg./min. per 1.73 sq.m. is shown for the first year of life, and in Figure 3B the same data are given for the older children. It is apparent that there is much greater scatter of the values for Tm_{PAH} than of those for G.F. or P.F. While the lowest figures obtained, around 3 to 15 mg./min. per 1.73 sq.m. surface area, are seen in the youngest infants (under one month of age), relatively high values are obtained in other infants of the same age. Several already have adult values within the first six months. After 15 months of age the values are comparable to adult values with very few exceptions.

On casual inspection the graphic charts of the data for G.F. and P.F. appear similar, as if

FIG. 2B. EFFECTIVE RENAL PLASMA FLOW IN OLDER CHILDREN
Symbols as in Figure 1A.

FIG. 3A. MAXIMAL TUBULAR EXCRETORY CAPACITY FOR PAH IN INFANTS
Symbols as in Figure 1A.

the rate of increase of these two physiological factors with aging were identical. Actually, this is not the case as can be seen from the figures on the F.F. ($100 \times \text{G.F.}/\text{P.F.}$) throughout this

age span (Figure 4, upper section). If the rate of increase in these two values were identical, then the F.F. would be a constant value and similar to the average adult value of 19.6%. As can

FIG. 3B. MAXIMAL TUBULAR EXCRETORY CAPACITY FOR PAH IN OLDER CHILDREN
Symbols as in Figure 1A.

be seen, this is not the case; for there is a considerable variability of the F.F. throughout the age groups. While several of the values are within the adult range early in life, and occasionally the F.F. is even low in the latter half of the first year, on the average a larger number of higher values are obtained in the first two years. In fact, some high values are found up to the eighth year of life. The average value for the F.F. in children is thus higher than that reported for

adults. It might be stated that the fluctuations rate of P.F. are normally wider than those G.F., being subject to situations which affect general circulation, and might thus account for some of the variations of the G.F./P.F. It must be pointed out that our clearance periods are short and represent "spot" clearances. It remains the possibility of error in estimating P.F. in the very small infants, an error which would produce false low values. If the blood

Middle section: $G.F./T_{mPAH}$.

Lower section: $P.F./T_{mPAH}$.

The ordinate scales are logarithmic, so that equal deviations of the numerator and of the denominator of each ratio from the average will produce equal distances from the line representing the mean. The solid line in each section represents the mean observed in adults (12); the broken line in each section represents the mean observed in the series of children here reported, calculated separately for infants under one year and for children over one year of age. The dotted lines represent one standard deviation from the mean, calculated for the present series.

level of PAH is too high for complete extraction in one circulation through a kidney with a very low Tm_{PAH} , complete extraction of the PAH circulating through the kidney would not occur, thus the PAH clearance in an immature child may be lower than the actual renal plasma flow. It is possible that in some of our small infants, as well as in some of the cases published by others, the PAH load exceeded the tubular excretory capacity, so that falsely low values for P.F. were produced. Data on the PAH extraction ratio in the very small infant are needed to clear this point. The PAH loads were calculated for the 10 youngest infants on whom the plasma flow has been determined in the present study. All the children older than these ten had a Tm_{PAH} well capable of excreting ordinary loads. The infants, E. S. (ten days old), K. C. (19 days old), and A. Y. (19 days old), had loads which would have required a Tm_{PAH} of at least 10 mg./min. per 1.73 sq.m. to assure complete PAH extraction (assuming that complete extraction occurs when $\frac{\text{load (PAH)}}{Tm_{PAH}}$ is less than 0.5); the loads of L. C.

(two days old), R. B. (20 days old), and J. S. (81 days old), were low enough to be excreted with a Tm_{PAH} as low as 2–5 mg./min. per 1.73 sq.m. The remaining four infants in this group had higher loads of PAH, but their Tm_{PAH} was determined and found to be high. Actually, only one infant in the group was observed to have a Tm_{PAH} below 10 mg./min. per 1.73 sq.m.

In order to determine the relative rates of maturation of glomerular and tubular function we have calculated the G.F./ Tm_{PAH} ratio on each child (Table I, column 19 and Figure 4, middle section). The scatter of the data is too wide to draw valid conclusions as to the comparative rates of maturation of these two functions. In general, the G.F./ Tm_{PAH} ratios (normal for adults taken as 1.72) show a wider variation in the infants under two years of age than seen later. Most of our very high values are seen in this younger age group. After two years of age the values are rarely significantly different from adult values.

The amount of renal plasma flow per unit of tubular excretory capacity as measured by the ratio P.F./ Tm_{PAH} is quite variable and evidences

CORRELATION OF UREA CLEARANCE AND FILTRATION RATE

FIG. 5. UREA CLEARANCE, C_m , IN CC/MIN., PLOTTED AGAINST GLOMERULAR FILTRATION RATE

The diagonal line represents a ratio of urea clearance to G.F. of 57.5:100. Each dot represents the average value in an individual child.

the wide variation found in Tm_{PAH} and possibly of the normal fluctuations in P.F. (Table I, column 18 and Figure 4, lower section). In older children the P.F./ Tm_{PAH} ratios are more constantly near the adult value.

The urea clearance values of this same group of children are listed according to age in Table I, columns 8 and 9. The wide variation in urea reabsorption accounts for the variable urea clearance values. Figure 5 shows the relationship between urea clearance and glomerular filtration rate with a correlation coefficient of 0.87. In individual cases the urea clearance varied between 34% and 81% of the mannitol clearance. This great variability has also been observed in adults.

DISCUSSION

It is unfortunate that we could not have collected maturation data in the same individual over the span of childhood,⁵ so that the comparative rates of maturation of the various functions could be determined more precisely. Our data lend themselves only to comparing the average developmental state of one renal function to that of another at a given age.

While, in general, the G.F., P.F. and Tm_{PAH} , when corrected for surface area, reach adult values somewhere around the second year of life, there are exceptions and, as would be expected, these various functions mature at different rates, so that in one child one function has reached maturity while another is still immature and the reverse may occur in a second child. Examination of the simultaneous ratios for these three variables shows certain trends in comparative maturation. It is apparent from the high F.F. (Table I, column 15 and Figure 4, upper section) that G.F. is at a higher level of maturity than P.F. in many of the younger children, though not all. This tendency toward a high G.F./P.F. ratio persists through the second or third year and in some instances later. West and his group (5) have also shown that this ratio is high in most of their infants under two years of

age and Barnett *et al.* (6) in examining premature infants found the F.F. to be even more consistently above that of the normal adult than apparent in the series of full-term and older infants reported here. Elevation of the intraglomerular capillary pressure (as seen in essential hypertension [12]) may exist in infants to account for the high F.F., but this has not been demonstrated. Whether the low serum protein concentration in the small infant is a factor in the increased F.F. can only be conjectured.

The G.F./ Tm_{PAH} ratios (Table I, column 17 and Figure 4, middle section) show a wide scatter. As with F.F., most of the extremely high and low values occurred within the first two years of life. After that time there is less irregularity and only an occasional high value. The few really high values occur in the first eight months of life. However, because of the irregularity of the data one would hesitate to draw a curve to show the trend of relative maturation of G.F. and Tm_{PAH} . The scatter in the ratios is chiefly dependent upon the very variable figures for Tm_{PAH} as the values for G.F. follow a much smoother growth curve. The data obtained by Barnett *et al.* (6) suggest that in premature infants high G.F./ Tm_{PAH} ratio may be a more consistent occurrence. The high figures obtained by West and his co-workers (5) were also observed in the youngest infants. These data suggest that a higher order of maturation of G.F. than of Tm_{PAH} exists in the first months of life but this is by no means constant for in fact, none of our children under six months of age had a G.F. within the adult range, whereas several had a Tm_{PAH} within the adult range at this time.

The irregularity in early life of the other ratios discussed is also apparent in the P.F./ Tm_{PAH} ratio. No definite trend in relative rates of increase in the P.F. and Tm_{PAH} can be noted from the data (Table I, column 18 and Figure 4, lower section). The data of West *et al.* (5) also show greater variability in the younger infants. Whereas, there is a gross correlation between the rate of increase in P.F. and the maturation of Tm_{PAH} , both reaching adult values at about two years of age, the maturation rate of the plasma flow seems steadier and follows a smoother curve. The tubular function of excreting PAH in pre-

⁵ Two infants in the group were studied on repeated occasions: B. K. at 10 and 55 days of age, and E. D. at 22 and at 54 days of age. In both infants the Tm_{PAH} (absolute values) remained stationary over the interim period, while the G.F. increased slightly in B. K. and considerably in E. D.

young infant does not seem to be limited by an inadequate blood supply.

The urea clearances were done simultaneously with mannitol clearances (under the influence of mannitol diuresis); therefore, the urea clearance values are probably higher than would be usual for these children.

It has been suggested (4) that the low G.F. in the young infant is dependent upon the resistance to filtration offered by the visceral layer of Bowman's capsule, which in the small infant is composed of cuboidal cells in contrast to the thin flat cells of the adult membrane (13, 14). The finding of high F.F.'s in many of these infants indicates that, contrary to the above assumption, a higher proportion of the plasma flow is filtered through the infantile glomerulus than through the adult one and, therefore, the thicker cell of the membrane in itself presumably does not reduce the rate of filtration. It is not unreasonable to postulate that the small size and number of capillary loops in the immature glomerulus (13) may account for the decreased blood flow through the glomerulus and thus the decreased G.F. The smaller number and size of capillary loops also offer a smaller filtering surface than the glomerular tufts of the adult, although in relation to the volume of the capillary bed (which influences the blood flow) the filtering surface in these immature glomeruli may be larger than in mature glomeruli. Whether the anatomical difference is the total or even a prime factor responsible for the low G.F. is not known. It is interesting, nevertheless, that both the functional maturation and the anatomic maturation of the kidney glomerulus occur at about the same time, around the second or third year of life (14). Low blood pressure in the small infant could possibly influence the G.F. but G.F. increases over a period of several months when the arterial blood pressure is more or less constant, indicating a lack of correlation between these two. Salmi (15) and Taussig (16) have shown that the arterial blood pressure in infancy changes very little from one week of age until four years of age. The anatomical fact that throughout childhood, and particularly in infancy, the ratio of the renal cortex to the medulla is lower than in the adult (14) might lead us to expect a low G.F./T_{MPAH} ratio. However, our figures do not substantiate such an expectation; an indication

that even the mass of tissue in the early months of life is not closely correlated with function.

Throughout these calculations of renal clearance we have correlated the data collected in the infants and children to adult values using surface area as the basis for comparison, as the principle of correlating renal function to surface area has been widely accepted (5, 17-19). Since this may not be the best point of reference, we have also given the absolute values. In order to determine if surface area is the best basis of comparing the G.F. in the growing child to that of the adult, we have related in Table II the G.F. (in cubic centimeters per minute) at different ages throughout childhood to several different measurements of reference: such as (1) body weight in Kg., (2) body height in cm., (3) body surface area in sq.m., (4) average kidney weight in Gm., and (5) average basal metabolic rate in calories per hour, and have compared these ratios to the adult values. The values for average kidney weight in the different age groups were obtained from the data of Peter (14), and the average values for basal caloric expenditure per hour were obtained from Washburn and Iliff (20). It is apparent that when body weight is used as the measurement of reference, the data are very irregular. In many of the smallest infants the values are above the adult range and after six months of age they are considerably above this level with a gradual decline of the values from a high point during the second and third years of life. When body height is used as reference, there is a gradual increase in the G.F. with growth and the irregularity is less marked than with body weight. However, under these circumstances the values in older children are still much below adult values and this seems unreasonable in the face of other evidence of renal functional maturity in this age group. When surface area is used as standard, occasional adult values are reached around six months of age but the values are not consistently in the adult range until about the second year. Using basal caloric expenditure as reference, there is little change throughout the first six months. After this age the trend is irregularly upward. This increase is slower than the rise seen when surface area correction is used, as might be expected considering the fact that children have a higher basal metabolic rate per sq.m. surface area than adults.

When kidney weight is used as reference, there is a gradual increase of the G.F. per unit of kidney mass, with maturation being reached between the fourth and fifth months of life. After this age and throughout childhood the values more closely parallel the adult values than when any other measurement of reference is used. This is the more remarkable since the values for kidney weight and basal metabolic rate at different age levels represent average values obtained from the literature, whereas, the weight, height, and surface area were measured in the individual patients, who in many instances deviated considerably from average standards.

It has been shown that the mannitol/inulin clearance ratio may be less than one (21). This fact does not invalidate the above data since the same procedure (mannitol clearance) was used in all the age groups and the values were compared to adult values obtained with the same substance (12).

SUMMARY

1. The glomerular filtration rate, effective renal plasma flow, tubular excretory capacity for PAH and urea clearance have been measured in 63 normal infants and children between the ages of two days and 12 years in order to determine the maturation rate of these individual renal functions.

2. In general, when corrected to standard adult surface area, the clearance values were lowest in the smallest infants and gradually rose to reach adult values around the second year of life. Maturation was most rapid in the first six months, then proceeded more slowly. The youngest child in whom all functions were within the adult range was seven months of age. The average child, however, did not show complete maturation of all functions studied before the end of the second year, although individual functions, particularly TM_{PAH} , were often found to be mature at a much younger age.

3. G.F. was found to be closely correlated to adult values after the first few months of life when kidney weight is used as the basis for comparison. When body weight and height are used as the basis for comparison, the data are very variable and show no regular maturational trend. When the surface area is the basis of reference, the maturation rate seems slower than when kidney weight is used. Since in the literature the surface area

is most commonly used as the basis for comparison with adult values, our graphic charts have been constructed using surface area correction.

4. Simultaneous ratios of the various functions were calculated to show relative rates of maturation. In general, it might be said that the ratios show wider variability in the early part of life than later on. The data indicate that these individual functions develop at irregular rates; one function might reach maturity in a given child earlier than another, and in a second child the reverse may occur.

a. There is a tendency toward high filtration fractions (G.F./P.F.) in the early months of life which continues through the second and third years.

b. The rate of Tm_{PAH} maturation is extremely irregular, resulting in great irregularity in the ratios in which Tm_{PAH} is involved.

c. Several of the children under two years of age had a rate of P.F. closer to the adult range than was the Tm_{PAH} (high P.F./ Tm_{PAH} ratio) but this high ratio was also occasionally seen in older children. In most of the determinations even in the very young infants the P.F./ Tm_{PAH} ratio was close to adult values to show roughly parallel rates of maturation.

d. The various ratios estimated would suggest that there is a tendency for G.F. to be more mature in the youngest infants than the other functions measured.

THE CEREBRAL BLOOD FLOW IN MALE SUBJECTS AS MEASURED BY THE NITROUS OXIDE TECHNIQUE. NORMAL VALUES FOR BLOOD FLOW, OXYGEN UTILIZATION, GLUCOSE UTILIZATION, AND PERIPHERAL RESISTANCE, WITH OBSERVATIONS ON THE EFFECT OF TILTING AND ANXIETY¹

By PERITZ SCHEINBERG² AND EUGENE A. STEAD, JR.

(From the Department of Medicine, Duke University School of Medicine, Durham, North Carolina)

(Received for publication March 18, 1949)

The nitrous oxide technique for the semiquantitative measurement of cerebral blood flow devised by Kety and Schmidt (1, 2) has made it desirable to restudy the cerebral circulation in man in various physiologic states. By measuring arterio-internal jugular differences of oxygen and glucose, the relation between changes in cerebral blood flow and cerebral metabolism can be observed. The purpose of this report is to record our findings in the use of the nitrous oxide technique in 33 observations on 20 normal young men; in the comparison of certain cerebral metabolic functions on 14 normal young men in the supine and erect postures; and in observations on the effects of apprehension on the cerebral circulation.

METHOD

Seventeen of the 20 subjects were normal, male medical students; the other three (W. Mc., D. M., and R. H. in Table I) were hospital patients who showed no evidence of disease. All the subjects were studied in the fasting state. Following local procainization, a 19 gauge, 6.5 cm. needle was inserted into the right internal jugular bulb in the manner described by Myerson (3), and an arterial needle was inserted in the right femoral artery. Following this the patient was allowed to lie quietly for 40 to 50 minutes before the procedure was continued.

The essential nature of the experiments ascribed in all theoretical details to the nitrous oxide method described by Kety and Schmidt (1, 2), but the mean arterio-venous nitrous oxide difference for the 10 minute period was measured differently. Instead of drawing five separate, simultaneous samples from the artery and vein for the plotting of the nitrous oxide curves, simultaneous continuous samples (called integrated samples) were drawn from the artery and vein into heparinized, oiled syringes

at the rate of 0.25 ml. every 7.5 seconds for the entire 10 minute period of gas inhalation. That this can be done accurately was demonstrated by drawing similar integrated samples simultaneously from the two femoral arteries in four subjects while the subject breathed the nitrous oxide mixture; the mean nitrous oxide content of these samples were identical in each subject. When the collection of the integrated samples is complete, the gas is continued for another 20 seconds while simultaneous samples of 6 ml. each are drawn from the artery and vein. These are used for the determination of the level of the arterial and venous nitrous oxide contents, respectively, at the end of 10 minutes of inhalation. The venous sample represents the cerebral nitrous oxide concentration per gram of brain, since after 10 minutes the interjugular blood and brain nitrous oxide should be in equilibrium and the solubility coefficient for nitrous oxide between blood and brain has been shown to be about 1.0 (4). The arterial sample serves as an internal check on the accuracy of the procedure. It should closely agree with the venous sample at that point, since in normal subjects the arterial curve has almost always flattened out at 10 minutes, and equilibrium between arterial and cerebral venous blood is approaching; lack of agreement indicates technical error, poorly-placed venous needle, unsteady gas administration, any of which would invalidate the observation. In our experience, the agreement in each instance has been close, the greatest variation being 0.44 volumes % nitrous oxide in a subject with relatively slow flow, and the average variation in 49 terminations being 0.24 volumes %. The nitrous oxide mixture is always given in such excess that only an extremely gross leak could alter the determination. It is felt that this is probably of small import actually, for our figures have not varied in subsequent patients, in whom a self-retaining mask was used. The potential advantages of the integrated sample technique will be dealt with at the end of this section.

The blood samples were placed in ice immediately after being collected, the usual precautions having been taken to assure the absence of air bubbles. The pH of the integrated arterial sample was measured with a glass electrode by means of a Beckman pH meter immediately after each blood flow.

¹ This work was supported by a grant from the Anna M. Hanes Research Fund.

² Holder of American College of Physicians Clinical Fellowship 1948-1949.

The subject was allowed to remain supine for 20 to 25 minutes following the first blood flow; then the table was tilted so that the subject stood erect at an angle of 65° to the horizontal. In this position the weight was supported partially by the legs and partially by leaning against the table. When the subject's blood pressure and pulse stabilized, and he showed no signs of ensuing syncope, the same procedure of gas inhalation and blood withdrawal was performed. The patient was then put supine, and if he was not uncomfortable or tired, a third flow was done after a wait of 25 minutes.

The arterial pressure was measured by auscultation every two minutes during the supine flows and every minute during the erect. In both positions measurement was always done with the subject's arm held at approximate heart level. From these readings average mean pressures were computed by adding one-third of the pulse pressure to the diastolic pressure. This method is in use in other laboratories, and observations here have shown that the mean pressure calculated in this way is about the same as that measured by the Hamilton manometer. In 91 observations in this laboratory the mean pressure calculated by adding one-third of the pulse pressure to the diastolic pressure on the manometer tracings varied on the average of 3 mm. Hg from the mean pressure calculated by the planimeter method. In order to have altered the accuracy of our comparisons of cerebral vascular resistance in the supine and erect posture, the error in mean arterial pressure would have had to be in the neighborhood of 25 mm. Hg, and consistently so. The pulse rate was measured every two to three minutes. Internal jugular venous pressures were measured by means of a spinal fluid manometer; the zero point was considered to be the needle level.

Arterial and venous samples were drawn simultaneously before and after each flow for glucose determinations, which were done by Nelson's photometric adaptation of the Somogyi method (5). The average of the two A-V glucose differences for each flow is used as the result.

In seven instances, single samples, drawn before and after the flows, were analyzed for oxygen by the Van Slyke manometric method (6) and averaged. In all other instances, oxygen determinations were made on the integrated blood samples by means of the Beckman spectrophotometer, using the method described by Hickam and Frayser (7).

The blood samples were analyzed for nitrous oxide by Kety's modification (2) of the original method of Orcutt and Waters (8). Here again certain modifications were made to suit our needs. The determinations were done on two different machines by two technicians, serving as checks on each other. The results were discarded if the calculated cerebral blood flows from the two machines did not agree within 10%. In all but three instances the flows agreed within 7%. Five ml. blood samples were used in the analyses on the integrated arterial and venous samples. This was done in order to give a larger volume of gas and thus render the difference of the manometer readings between the arterial

and venous samples 2.5 times as great as with 2 ml. samples, and accordingly reduce the percentage error of the individual determinations. The mean arterio-venous nitrous oxide difference must be determined carefully, for a variation in this difference of 0.01 volumes % is equivalent to a variation of 0.09 volumes % in the final venous nitrous oxide sample. Samples of internal jugular blood, drawn immediately before each flow, were used for the blank determination. The difference between the blank samples on the same individual were negligible; it never varied more than 0.25 volumes %. A sample determination is as follows:

Blank = 1.23 volumes %,

Integrated arterial sample = 5.34 volumes %,

Integrated venous sample = 4.53 volumes %,

Mean arterio-venous nitrous oxide difference for 10 min. = 0.81 volumes %,

Single venous nitrous oxide sample at 10 min. (V_t) = 5.05 volumes %,

Single arterial nitrous oxide sample at 10 min. (A_t) = 5.19 volumes %.

The cerebral blood flow can be calculated simply from these data:

$$CBF = \frac{5.05}{0.81 \times 10} \times 100 = 62 \text{ ml./min./100 gm. brain.}$$

The factor 100 is to convert the answer to units of per 100 gm. of brain, to be consistent with other data in the literature. The factor 10 converts the mean arterio-venous nitrous oxide difference per unit time (one minute) into the total mean arterio-venous nitrous oxide difference for the entire 10 minute period. The denominator is thus equivalent to Kety's expression $\int_0^{10} (A-V) dt$. In 49 complete cerebral blood flow analyses done by two technicians on different Van Slyke machines, on normal supine subjects, the following mean figures were obtained for the integral parts of the formula: $\int_0^{10} (A-V) dt = 7.11$ volumes per cent; $V_t = 4.68$; $A_t = 4.92$ with standard errors of 0.30, 0.05, and 0.09 respectively.

In this study the direct measurement of the mean arterio-venous nitrous oxide difference has the following advantages over the calculations of the mean difference from five separate samples: (1) Since only five Van Slyke analyses (and checks) are required for each blood flow (11 analyses [and checks] are required for the original method), several blood flows can be done the same day without straining the laboratory facilities. (2) It seemed more accurate to allow the body to integrate the samples than to draw curves through individual points. (3) Smaller quantities of blood can be used if necessary.

It is important to keep in mind that the nitrous oxide method measures only the mean cerebral blood flow over the 10 minute period of gas inhalation. Results obtained when the flow might be changing must be interpreted in that light; otherwise erroneous conclusions may be made. For example, if a subject had an abnormally rapid blood flow during the first five minutes of the observation, the nitrous oxide content of the cerebral

venous blood may have reached or approached equilibrium with the nitrous oxide concentration of the brain at five minutes rather than 10 minutes, so that even if the blood flow fell to a very low level during the second five minutes, the analyses of the bloods would show a small mean arterio-venous nitrous oxide difference, and the flow would be calculated as being rapid. In studies on erect subjects, it is possible that the cerebral blood flow was falling progressively during the entire time, in which case an accurate mean flow for that period could be calculated. If, however, the flow was stable for the first six to eight minutes, and then fell rapidly during the last two to four minutes, the recorded blood flow would be calculated falsely high. It would seem, therefore, that if there is a mistake in our comparison of the supine and erect flows, it is that the average flow in the erect posture was actually lower than we have recorded it, and that the difference between supine and erect flows is even greater than our figures indicate. This can be checked by drawing cerebral arterio-venous oxygen differences before and after the flow, which we did in five instances, as mentioned in the results. If the flow falls progressively the integrated arterio-venous oxygen difference will be equal to the average of those drawn before and after. In our five subjects this was true. The formulae for the calculation of various metabolic functions discussed in this paper are given below:

$$\text{Cerebral O}_2 \text{ consumption (CMR O}_2\text{)} = \text{CBF} \times \frac{A - \text{VO}_2}{100}$$

in ml. O₂/min./100 gm. brain.

$$\text{Cerebral glucose consumption (CMR gl.)} = \text{C} \times \frac{A - \text{V glucose}}{100} \text{ in mgm. glucose/min./100 g brain.}$$

Cerebral vascular resistance

$$(\text{CVR}) = \frac{\text{mean arterial pressure}}{\text{CBF}}$$

in mm. Hg/ml. blood/100 gm. brain/min.

RESULTS

Normal Values. The essential data are given in detail in Tables I and II. The cerebral blood flow supine varied from 50 to 103 ml./min./100 g. brain. Our mean figure for cerebral blood flow is 65 ml./min./100 gm. brain (standard error 2.1) this is a significant difference statistically from the mean of 54 (standard error 2.1) reported by Kety (2), as indicated by the small standard errors of the two groups. The reasons for this difference are not clear: The average age of the subjects or differences in the techniques in the two laboratories may be responsible. The cerebral arterio-venous oxygen differences supine varied from 4.4 to 7.6 volumes % with a mean of 6.0, the mean reported by Kety is 6.3. The cerebral oxygen utilization ranged from 3.1 to 5.2 . .

oxygen/min./100 gm. brain. The mean figure for cerebral oxygen utilization obtained here was 3.8 ml. oxygen/min./100 gm. brain, while that obtained in Kety's lab was 3.3. The difference is due to the difference in the figures for cerebral blood flow. The other values are quite similar to those reported from other laboratories (9-12).

The cerebral vascular resistance in the supine position ranged from 0.86 to 1.93, with a mean of 1.31. The cerebral vascular resistance has been given as the quotient of the $\frac{\text{mean arterial pressure}}{\text{cerebral blood flow}}$,

disregarding the internal jugular pressure. Only preliminary observations on internal jugular pressure were made; further studies are now in progress and will be reported at a later date. The available measurements indicate that the average fall in internal jugular pressure on assuming the erect posture is 60 mm. water.

The cerebral arterio-venous glucose differences supine ranged from 6 to 16 mgm. %, and the cerebral glucose utilizations varied from 3.9 to 9.5 mgm. glucose/100 gm. brain/min. The ratios of cerebral arterio-venous glucose difference to ar-

terio-venous oxygen difference varied from 1.10 to 2.46, a mean of 1.67. The variations are probably related primarily to the method of glucose determination. It is interesting that, although the expected ratio is 1.34, the figure obtained in this study corresponds closely to that of 1.62 obtained by Gibbs *et al.* (12) in 50 determinations on 25 schizophrenic and epileptic patients. There is no evidence for altered cerebral metabolism in such subjects (13). There is no indication that inhalation of 15 per cent nitrous oxide alters this figure. Since our present knowledge of normal brain metabolism is incomplete, as recent studies (14) have demonstrated, it may well be that the ratio of 1.34, anticipated from the chemical equation of the complete breakdown of glucose to carbon dioxide and water is inaccurate. Though oxygen: carbon dioxide ratios have indicated a cerebral R.Q. of about 1.00, it is entirely possible that other mechanisms, such as the partial oxidation of glucose to pyruvic and lactic acids, and the conversion of

carbohydrate to fat, may fortuitously place the figure at 1.00.

Apprehension. The effect of apprehension on cerebral blood flow is summarized in Table II. The criteria used to determine apprehension were (1) clinical observations, (2) rapid pulse, and (3) elevated systolic pressure. Those subjects who were considered to be apprehensive had a range of cerebral blood flow from 370 to 700 ml./min. sq.M. body surface; those who were not considered to be apprehensive had a range of 382 to 638. There is no significant difference between the means of these two groups.

Posture. The effects of changing the subject from the supine to the erect position are summarized in Table IV. The mean cerebral arterial pressure in the erect position was calculated by subtracting from the mean erect brachial arterial blood pressure the vertical distance in mm. Hg from the second rib to the mid-cerebrum. This can easily be calculated since the patient's angle to the horizontal plane is known. Although we did not make direct measurements of the carotid pressure in the erect position, it is felt that the application of hydrostatic laws to the circulation justifies this assumption. Measurements of common carotid arterial pressure with the subjects in a vertical head-up position by Loman (15) showed a mean fall of 20 mm. Hg in 23 observations. This figure closely corresponds with our calculated one of 22 mm. Hg fall, if it is considered that our subjects were only tilted to 65° and that the mid-cerebrum is about 15 cm. cephalad to the point at which Loman and his group were measuring.

The cerebral blood flow in the erect position varied from 40 to 81 ml./min./100 gm. brain, with

* P value of 0.02 or less is considered significant.

a mean of 52. This represented a 21% fall in cerebral blood flow over the supine position. This is a highly significant change statistically. Observations reported by Shenkin *et al.* (16) using the nitrous oxide technique showed no fall in cerebral blood flow in five normal persons tilted head-up 20° from the horizontal.

The cerebral arterio-venous oxygen difference in the erect position ranged from 5.4 to 9.8 volumes %, with a mean of 7.4 volumes %. This represents an increase of 23% over the supine position, a highly significant change statistically.

The cerebral oxygen utilization, cerebral arterio-venous glucose difference, cerebral glucose utilization, and $\frac{A-V \text{ glucose}}{A-V \text{ oxygen}}$ ratio did not change significantly.

The effective mean cerebral arterial pressure fell an average of 34% from the supine to the erect position. The vertical distance from the second rib to the mid-cerebrum in our subjects averaged 22 mm. Hg; the average fall in mean auscultatory pressure on standing erect was 7 mm. Hg. The cerebral vascular resistance in the erect position ranged from 0.90 to 1.62, with a mean of 1.12. This represented an average fall of 16% from the supine position, a highly significant change statistically.

Because other studies have pointed out the fall in cerebral blood flow associated with over-ventilation (17) the arterial blood pH was measured after each blood flow. There was no difference between the pH in the supine and that in the erect posture, indicating that the observed alterations in cerebral metabolism during posture change were not related to changes in respiration, insofar as these changes could be measured by the blood pH.

In five instances, cerebral arterio-venous oxygen differences were measured when the subject was first tilted erect and again just before he was put supine, as well as from the integrated samples. In every instance the arterio-venous oxygen difference increased during the period of the flow, indicating the value of the integrated samples for accurate calculation of mean cerebral oxygen utilization.

COMMENT

The values for the various normal metabolic functions of the brain vary over a wide range

from person to person, and these variations are not altered significantly by relating the values to the surface area of the patient. Statistical analysis of available anatomical data of brain weight and surface area (18) reveals that the correlation coefficient of these figures is between 0.45 and 0.50, roughly in the range of correlation of other biological variables. The variations from individual to individual of the values for cerebral metabolic functions seem to be due to two causes: (a) much of the variation is probably real, just as there is known to be individual variations in other physiologic functions, and (b) technical errors are probably partially responsible, as are minor anomalies in the anatomy of the internal jugular circulation. There seems to be no way of predicting at present whether contamination of the jugular blood by a vein draining the subcutaneous and deep tissues of the face would erroneously raise or lower the calculated cerebral blood flow. If arterio-venous shunts in the skin were open and contributed to the contamination, the figure would be falsely high; if the contaminating vein drained only areas of fat, the figure might be falsely low. Studies to clarify this problem are in progress.

The accumulated data on normal individuals seem to indicate that the rate of cerebral oxygen utilization during the time of the experiment is a fairly constant figure in any given person, and that, lacking clinical signs of cerebral dysfunction, the cerebral arterio-venous oxygen difference increases as the rate of blood flow falls. The alterations in cerebral blood flow and cerebral arterio-venous oxygen difference on assuming the erect posture are of similar magnitude (−21% and +23% respectively) but in opposite directions, so that the rate of cerebral oxygen utilization remains the same. The same relationship would be expected to hold for cerebral blood flow and arterio-venous glucose difference, but technical inaccuracies involved in performing the analyses for blood glucose obviate any definite conclusions on this score at present.

The ability to maintain a stable rate of oxygen utilization under most conditions exists in the liver (19) as well as the brain. The kidney, on the other hand, does not behave similarly, but maintains a fairly constant arterio-venous oxygen difference in the face of a considerable fall in blood flow (20). Under certain conditions of duress, the

brain also behaves differently; Kety and co-workers have shown that in insulin hypoglycemia the cerebral blood flow remains stable, while the cerebral arterio-venous oxygen and arterio-venous glucose differences fall strikingly, giving lowered rates of cerebral oxygen and glucose consumption (21).

We have compared this group of normals with a group of similar individuals studied by Stead *et al.* (22), on whom the cardiac index in the resting state was determined. It seemed fair to make this comparison because of these reasons: (a) The subjects were, in both instances, mainly normal medical students and were studied under similar conditions; (b) The average surface area in the two groups was almost identical (1.87 sq.M. in Stead's study and 1.92 sq.M. in this study); the size of the groups was also the same; and (c) the addition of another procedure, such as the measurement of the cardiac output, to that of measuring the cerebral metabolism, would almost necessarily obviate the existence of a basal state in the subjects. Table V summarizes these com-

TABLE V
Relationship of cerebral blood flow and cerebral O₂ consumption to cardiac output and total O₂ consumption

Cardiac index (l./min./sq. M.)*	3.3
Cerebral blood flow (l./min./sq. M.)	0.463
% Cardiac output to cerebral circulation	14%
Total O ₂ consumption (ml./min./sq. M.)*	128
Cerebral O ₂ utilization (ml./min./sq. M.)	27.8
Cerebral O ₂ consumption as percentage of total O ₂ consumption	22%

* Stead *et al.* (22); see text for explanation.

parisons. Our calculations were made on the basis of an average brain weight of 1400 gm. Since we were comparing two different groups, only comparisons of means could be made. The data indicate that approximately 14% of the cardiac output in the resting state is devoted to the cerebral circulation, whereas the cerebral oxygen consumption is about 22% of the total oxygen consumption of the body. If the figures given by Kety and Schmidt (17) for percentage of cardiac output devoted to cerebral circulation and cerebral oxygen consumption as percentage of total oxygen consumption are recalculated using 1.0 as the solubility coefficient of nitrous oxide between brain and blood, the resultant averages of 15% and 19% closely approximate our results. It should be

pointed out that this agreement appears to be fortuitous, for their figures for cardiac output, measured by the ballistocardiogram, are moderately lower than those usually given in measurements done by the direct Fick principle.

The finding that the cerebral blood flow is not altered in apprehension is of considerable physiological interest. Although Table III includes only cerebral blood flow, no correlation was found between apprehension and any aspect of cerebral metabolic function measured in this study. The cardiac output increases about 40% during apprehension (22, 23); it would be interesting to know where the blood goes in this condition. Apparently it does not go to the brain, kidney, or skin.

Although our studies have not revealed a quantitative relationship between alterations in the arterial pressure and cerebral blood flow in the same person, there was a definite fall in cerebral blood flow with the fall in effective cerebral arterial pressure on standing. The significance of the fall in cerebral vascular resistance in the erect posture cannot be interpreted with available data. There are at least two possibilities: (a) The cerebral vessels may actually dilate in response to a fall in arterial pressure or in response to whatever stimuli result from standing erect. Direct observations of the pial vessels of the cat through a Forbes window have shown that a fall in arterial pressure is a strong stimulus for the production of pial vasodilatation (24). (b) The fall in cerebral vascular resistance may be the result of a decrease in pressure on the venous side of the capillaries, since blood in the internal jugular system must certainly run down-hill when the subject is erect.

SUMMARY AND CONCLUSIONS

1. The nitrous oxide method for measurement of cerebral blood flow was used in 33 observations on 20 normal young men in the supine posture. Modifications in the original method are described.

2. Normal figures are given for cerebral blood flow, cerebral arterio-venous oxygen difference, cerebral oxygen utilization, cerebral arterio-venous glucose difference, cerebral glucose utilization, and cerebral vascular resistance.

3. In normal, resting subjects 14% of the cardiac output is devoted to the cerebral circula-

tion; 22% of the total oxygen consumption of the body is cerebral oxygen consumption. The significance of this is discussed.

4. Observations on apprehensive subjects revealed no difference in cerebral metabolic function from those who were not anxious.

5. Tilting normal subjects to the erect posture resulted in a 21% fall in cerebral blood flow, a 23% increase in cerebral arterio-venous oxygen difference, a 34% fall in effective cerebral arterial pressure, and a 16% fall in cerebral vascular resistance.

6. Cerebral oxygen utilization is a relatively constant figure in the normal person under ordinary stresses. Its buffer system is flexible, allowing the cerebral arterio-venous oxygen difference to compensate for relatively large changes in cerebral blood flow.

7. The fall in cerebral vascular resistance in the erect position may be the result of cerebral vascular dilatation or a decrease in pressure on the venous side of the cerebral capillaries.

ACKNOWLEDGMENTS

The authors are indebted to Dr. Seymour S. Kety and colleagues for instruction in the techniques utilized in this paper. These studies were done with the technical assistance of Mrs. Regina Spencer, Miss Frances Morgan, and Mrs. Louise Allen.

SEROLOGICAL STUDIES IN RHEUMATIC FEVER. II. SERUM COMPLEMENT IN THE RHEUMATIC STATE¹

By EDWARD E. FISCHER,² RUTH H. PAULI, AND JACK LESH

(From the Department of Medicine, Columbia University College of Physicians and Surgeons, and the Edward Daniels Faulkner Arthritis Clinic of the Presbyterian Hospital, New York City)

(Received for publication March 21, 1949)

In the study of rheumatic fever there has been disagreement and confusion as to the level of serum complement (C'). Veil and Bucholz (1), Coburn (2), Rachmilewitz and Silberstein (3), and others have reported a low complement content of the serum, which rises to normal with the subsidence of activity. This has been cited as possible evidence of the occurrence of an antigen-antibody reaction in rheumatic fever, perhaps related to a preceding hemolytic streptococcus infection. Predominantly normal or slightly low levels of C' in rheumatic fever were reported by Kellett and Thomson (4), and more recently by deGara and Goldberg (5). On the other hand, high values during the early period of rheumatic activity and low values later were noted by Hadjopoulos and Burbank (6). In this respect, rheumatic fever did not differ from several other febrile illnesses which they studied. The variety of results obtained by different investigators may be attributed in part to the variety of technics employed, and the lack of a reproducible quantitative method. The purpose of the present study was to reevaluate complement levels in rheumatic fever with the accurate quantitative method developed by Mayer, Osler, Bier and Heidelberger (7, 8), in which the 50 per cent hemolytic unit is determined spectrophotometrically in the presence of adequate concentrations of Mg⁺⁺ and Ca⁺⁺.

METHOD

Details of the analytical procedure as outlined by Mayer *et al.* (8, 9) were carefully observed since this is essential to obtain accurate and consistent results.

¹ Presented at the meeting of the Eastern Section, American Federation for Clinical Research, Philadelphia, December, 1948.

² This work was done during the tenure of a Life Insurance Medical Research Fellowship, aided in part by the Masonic Foundation Gift for the Study of Rheumatic Fever.

The diluent for all reagents was a barbiturate buffered sodium chloride solution (8) with the addition of 1.0 gm. magnesium chloride and 0.2 gm. of calcium chloride to the 2 liter stock solution. The stock solution was diluted 1 part up to 5 with distilled water to make an isotonic solution of pH 7.3-7.4. Sheep cells were obtained by sterile technic from the external jugular vein of sheep and preserved in sterile Alsever's solution (8). The suspension was kept at +2 to +5° C. and although some hemolysis occurred after three or four weeks, cells preserved in Alsever's solution and washed five times with buffered saline were no more fragile or susceptible to lysis than fresh cells, and yielded the same results as did washed fresh cells. After washing five times, buffered saline was added to the cells until a standardized suspension was obtained. Standardization was performed by lysing exactly 1.5 ml. of the cell suspension with 13.5 ml. of distilled water in a 15 ml. volumetric flask. The resulting solution was read in the Coleman Universal Spectrophotometer at 5500 Å and, when standardized in a 13 mm. square cuvette, gave a value of $D_{5500} = .560$, corresponding to an original cell concentration of about 660,000 cells per cu.mm. or approximately a 2 per cent suspension. The amboceptor was rabbit serum containing antibodies to sheep red cells (Lederle) titrated for minimal hemolytic potency in the presence of an excess of C'. Four minimal hemolytic units of amboceptor, an excess, were employed in each test. The amboceptor was appropriately diluted with buffered saline so that it could be mixed in exactly equal volumes with the standardized sheep cell suspension. The resulting mixture was incubated at 37° C. for 15 minutes. On lysis of 1.5 ml. of the sensitized and standardized sheep cell suspension with 6 ml. of distilled water, a value approximating $D_{5500} = .560$ was obtained. This value, obtained in duplicate, served as the standard for the point of 100 per cent lysis and as a reference for the degree of hemolysis in the experimental tubes.

Blood was obtained from rheumatic and other individuals at the Presbyterian Hospital, Babies Hospital, and the Pelham Home for Children. After clotting at room temperature for about two hours, the blood was centrifuged for 10-15 minutes at 2,000 RPM and the supernatant serum poured off. The serum was frozen immediately and kept in the CO₂ icebox until used. By storing sera in this way, repeated determinations were possible at different times and reproducible results were obtained after storage for seven months. Storage of serum in a mechanical deep freeze unit at -17° C. did

not preserve the C' activity. A loss of 25 to 33 per cent of the original C' activity of the sera occurred in one week at this temperature.

Tests were carried out in centrifuge tubes of 40 ml. capacity to allow thorough mixing. The addition of reagents to each tube was made with analytical precision in the following order: Exactly 1.5 ml. of the standardized sensitized sheep cell suspension, buffered saline to make a final volume of 7.5 ml. after all reagents are in the tube, and serum, diluted 1 to 100 with saline, in varying quantities from 1.0 to 6 ml. Each test was performed with three different concentrations of serum. In the majority of tests, amounts of 1.5, 2.0, and 2.5 ml. of diluted serum were satisfactory. After incubation at 37° C. for 40 minutes with frequent shaking, the tubes were centrifuged and the density of the supernates read in the Coleman Universal Spectrophotometer at 5500 Å. The density of the experimental tube divided by the density of a completely lysed control tube (approximately .560) gave the degree of hemolysis. The amount of complement was then determined by interpolation on the curve for the equation $x = (y/1 - y)^{1/n}$, where x = the amount of complement (C') in 50 per cent hemolytic units, y = the degree of lysis (7, 10). Preliminary tests with human complement showed that the factor $1/n$ equalled 0.2 as it had in the determination of guinea pig complement (8). Usually two, and occasionally all three, tubes containing the various amounts of test serum gave an amount of hemolysis between 10 and 80 per cent, and could be used for interpolation of the 50 per cent unit of complement. Not only was this a control of the tech-

nie at two or three different concentrations of serum, but it also permitted the detection of anticomplementary activity in the serum when increasing amounts of serum consistently showed proportionately less C' activity. This situation did not occur in the series of sera reported here.

*Error of technic:*² Repeated determination of the same samples of serum at different times gave values to within ± 1.08 units of C' (± 1 standard deviation) when the same concentration of serum was used in the repeated tests. The results of determinations at two different degrees of hemolysis (between 5 per cent and 80 per cent), *e.g.*, with different amounts of the same serum, gave values of ± 1.8 units, as did the results of determinations at three different degrees of hemolysis in the same hemolytic range. Since the test point employed was close to the range of 50 per cent hemolysis, the standard deviation of ± 1.1 units is applicable to the determinations reported.

RESULTS

The mean value for the C' content of 50 normal individuals aged five to 39 was 37.7 ± 3.9 50 per cent hemolytic units per milliliter of serum. The distribution of the values in the normal subjects is

FIG. 3. SERUM COMPLEMENT LEVELS BEFORE AND DURING AN ATTACK OF ACUTE RHEUMATIC FEVER

represented by the dotted bar graph in Figure 1. The C' content of the sera of normal individuals was maintained over a period of months with little variation.

Serial determinations of C' were done on the sera from 50 patients with rheumatic fever. The initial values of complement in these individuals irrespective of the duration of the active disease before coming under observation are shown in Figure 1. These values, and the subsequent determinations of C' during the course of the illness, are presented in Table I. At the time of the initial determination, the serum complement was in excess of 50 units and well above normal in 42 of the 50 patients; three others, with initially normal levels, had a subsequent elevation. Twenty-four patients were seen within two weeks after the onset of symptoms of rheumatic fever (Tables IA and B) and 20 of these had C' levels in excess of 50 units per ml. Of the four patients seen in the first two weeks in which the level was below 50 units, one (D. H.) had a normal level on the day of onset (39 units). In this individual, an abrupt increase in C' was observed four days later concomitantly with the development of more manifest symptoms and an elevation of the erythro-

cyte sedimentation rate. Another of the four patients seen early in the course of the disease with a C' below 50 units died shortly after a single determination revealed no C' activity. The other two patients with initial low levels (H. L. and C. B. in Table IB and Figure 2) presented low curves which gradually reached normal with the subsidence of activity. These two patients did not present any other unusual finding or differ clinically from the majority of patients having high complement levels. There was no evidence of an accompanying acute nephritis, as might be anticipated from the observation that several cases of acute glomerulonephritis presented low curves (11). These two patients, therefore, are the only ones which presented low C' curves. The complement curves of six other individuals are presented in Figure 2 and are representative of the curves of the 40 patients with elevated complement levels. It is apparent that complement is high initially and falls gradually to normal. This fall accompanies the subsidence of activity, as indicated roughly by the curve of the erythrocyte sedimentation rates (millimeters after one hour, Westergren method). Although many patients developed a rise in anti-streptolysin "O" titers, there was no correlation

with the rise and fall of serum complement content.

Six patients have been observed with complement determinations before a recrudescence of rheumatic activity (Table IA and Figures 3 and 4). An elevation of serum C' frequently preceded the onset or exacerbation of rheumatic activity either as a sequence of a sore throat, or as a manifestation of continuing subclinical rheumatic activity. The change in complement activity from the relatively normal state, with the onset of a hemolytic streptococcus infection and, subsequently, of rheumatic fever is seen in Figure 3. The patient, J. H., was being observed routinely in the follow-up clinic seven years after an attack of rheumatic fever and had a mild upper respiratory

infection due to an undetermined organism. Two months later, the patient experienced a streptococcus sore throat. The sedimentation rate rose, as did the complement level. With the occurrence of acute rheumatic fever ten days later, the serum complement remained elevated, with renewed elevation of the sedimentation rate. Observations to be reported show that many acute inflammatory illnesses such as acute pharyngitis are accompanied by an increase of serum complement (11). This increase abruptly subsides except in the few instances where active infection persists or, as in this instance, rheumatic fever develops. The character of C' levels in recurrent rheumatic attacks is also illustrated in the chart of three patients presented in Figure 4. These

children had had activity three to six months before the initial C' determinations. Despite the apparent subsidence of activity by the usual clinical and laboratory criteria at least three months previously, the first two children, J. M. and A. S., were kept on salicylates. Salicylate was then discontinued with recurrent manifestations of activity in both children. In the first patient, the C' was elevated before cessation of the salicylate and, in retrospect, can be considered an indication of continuing subclinical rheumatic activity. In the second individual a normal C' was present at the

time salicylate was discontinued but was elevated four weeks later. In the subsequent recrudescence, if such it may be called, no joint flare-ups, fever, or tachycardia accompanied the rise in sedimentation rate and C'. The third individual, H. G., had had an acute attack of rheumatic fever, which subsided promptly. The first observation of complement was done after discharge from the hospital and was somewhat elevated but the sedimentation rate was normal. After two months the ESR and C' were observed to be elevated and a tachycardia developed. No other manifestations were ob-

served at that time. Subsequently, a fulminating attack of acute rheumatic myocarditis developed which terminated with death two months later. It is probable that the initial observation of an elevated C' in this instance indicated continued subclinical activity, later becoming manifested by an elevated sedimentation rate as well, and then tachycardia, fever and frank myocarditis.

The presence of subclinical activity was also detected in the patient, A. A., of Table IA. This patient had had a rheumatic attack with prompt subsidence of activity two months previous to the first observation. The sedimentation rate was normal as was the complement content of the serum. Without any clinical changes, and with a continued normal sedimentation rate, the C' rose

FIG. 4. THE COMPLEMENT AND SEDIMENTATION RATE OF THREE PATIENTS WITH RECURRENT RHEUMATIC FEVER WHO HAD HAD SUBSIDENCE OF CLINICAL ACTIVITY THREE TO SIX MONTHS PREVIOUSLY

after one month to 53 units and later to 64. After four weeks of unexplained elevation of the serum complement a moderate but persistent tachycardia was observed and an abrupt elevation of the sedimentation rate occurred.

DISCUSSION

Serum complement has been of interest to many investigators who attempted to define the rheumatic state as an allergic type of reaction (1-3, 12). A diminution of circulating complement is found in certain experimental antigen-antibody reactions, both *in vitro* (13) and *in vivo* (14). Clinically, a diminution of serum complement has been reported in some cases of serum sickness (11, 15, 16). However, there are several causes for a low C' other than fixation by antigen-antibody aggregates. Decreased production of C' is said to occur in liver disease (17), and in terminal illnesses (18). Also, C' levels apparently may be diminished by the presence of inhibitory or anticomplementary substances in the serum. Anticomplementary sera are occasionally found in routine Wassermann tests, but the nature of the substances responsible for the inhibition or inactivation of complement is not clear. One such substance is gamma globulin, a relative preponderance of which causes serum to become anticomplementary (19). This study, employing a precise and reproducible technic, failed to confirm the reports of a low complement in 46 of 50 cases of rheumatic fever. Of four cases with a low C' content, two died shortly after the determination. The observation is in agreement with previous reports (17, 18) of a low C' preceding death in many conditions other than rheumatic fever. Two patients with rheumatic fever exhibited low complement curves (Figure 2, H. L. and C. B.). No evidence of an abnormal anticomplementary effect was found in the sera of these patients to account for the low C' activity but the diminution may have been due to an antigen-antibody reaction that occurred independently of the rheumatic process.

It is known that certain antigen-antibody reactions do not fix complement *in vitro* (20). In addition, in several known allergic reactions, with clinical manifestations similar to serum sickness, but caused by a simple chemical antigen, *e.g.*, sulfadiazine, a high complement level was found (11). Because these immunologic or allergic reactions

may occur without any apparent fixation or diminution in complement, the possibility remains that the rheumatic reaction may be allergic and yet fail to fix complement. It is therefore apparent that the allergic hypothesis for the development of rheumatic fever receives neither support nor refutation by the data presented, although evidence for the occurrence of an antigen specific for rheumatic fever has not been substantiated (21).

This study fails to confirm reports of a low or normal C' in patients with rheumatic fever. Indeed, an unexpected finding in the opposite direction was observed. An increase in C' above 50 units per milliliter was observed at some time in 45 of the 50 cases observed. The increase was particularly marked early in the course of the disease. Very few reports in the literature mention an increase in C' in acute inflammatory disorders (6, 22), possibly because the customary use of double dilution of serum (*viz.*, .01, .02, .04 ml. with a normal value of 0.02 ml.), does not permit increased C' activity to be noted except where the increase is 100 per cent or more above normal. In addition, maximal C' activity may have been prevented by the lack of optimal concentrations of Mg⁺⁺ and Ca⁺⁺ (8). Using the technic of Mayer *et al.*, a high C' was also found in a variety of other acute and chronic illnesses (11). The cause for the increase in C' activity is not apparent. Although the complement response in rheumatic fever does not appear to be specific for this disease, the mechanism of this increase warrants further study, as it may be concerned with resistance mechanisms. Serum complement is a complex of labile substances which apparently plays a part in resistance mechanisms of the host. It is instrumental in promoting phagocytosis of bacteria and probably has a wide range of more ill-defined activities (17, 23-25). The increase in C' in inflammatory conditions resembles somewhat other non-specific changes in the blood such as the elevation of the sedimentation rate and the appearance of the C-reactive protein of Tillett and Francis (26) (the acute phase protein).

The elevation of complement in most cases of rheumatic fever is related to the course of the disease. It may remain abnormally elevated with apparent subsidence of activity and the return to normal of other criteria such as the polymorphonuclear leukocyte count or the ESR. In these in-

stances it appears to be a more sensitive indication of continuing activity than the ESR. However, it is not an infallible aid because it, as well as the sedimentation rate, may occasionally be normal a few days before obvious clinical exacerbation occurs. Furthermore, the extent of increase in complement does not appear to be related to the severity of the disease process but may perhaps be related to the abruptness of the change from the normal to the pathological state. Further studies concerning the relationship of an increased C' content of serum to activity of the rheumatic process are in progress.

SUMMARY

1. Quantitative serial studies of total complement (C') in serum were made, using the spectrophotometric technic for the determination of the 50 per cent hemolytic unit in the presence of magnesium and calcium ions.

2. The range of complement in sera of 50 normal individuals was found to be 37.7 ± 3.9 units per milliliter.

3. Forty-five of 50 patients with rheumatic fever had an elevation of the serum complement above 50 units per milliliter of serum at the onset of the attack or shortly thereafter. Two patients presented a low complement which gradually became normal. Of the remaining patients, two others had a low C' and died, and one patient had a normal C' level determined when the disease process was beginning to subside.

4. The elevation of serum complement appears to be another criterion of activity of the rheumatic process.

5. The relationship of these observations to the hypothesis that the rheumatic state is of allergic origin is discussed.

EVALUATION OF THERAPEUTIC SUBSTANCES EMPLOYED FOR THE RELIEF OF BRONCHOSPASM. V. ADRENERGIC AGENTS¹

By ELLIOTT BRESNICK,² JOHN F. BEAKEY,³ LEON LEVINSON,⁴
AND MAURICE S. SEGAL⁵

(From the Department of Inhalational Therapy, Boston City Hospital, and the Department of Medicine, Tufts College Medical School, Boston)

(Received for publication March 31, 1949)

Many laboratory techniques have been employed in the study of sympathomimetic amines, particularly in an attempt to correlate chemical structure with pharmacological activity (1-7). In Table I are shown the structural formulae of the preparations dealt with in this report.

The technique of protection studies in asthmatic human subjects appears to offer an additional method of investigating and evaluating these and other substances in the ultimate test object, man. The technique essentially consists of the measurement of the protection afforded by any substance against the dyspnea and bronchospasm induced by repeated administrations of histamine, methacholine, or allergens, as measured, in part at least, by changes in vital capacity.

METHODS

The methods we have employed and their historical development have been extensively presented elsewhere (8, 9).

In the experiments reported at this time, the bronchospastic agents used were histamine diphosphate⁶ and methacholine chloride,⁷ employed intravenously or as aerosols. The protecting ability of the therapeutic agent under examination was determined by serial observations of the reduction in vital capacity produced by repeated administration of a constant dose (predetermined as capable of producing a consistent reduction in vital capacity

of at least 25 per cent) of histamine or methacholine at varying intervals after the protecting agent was administered. The degree of protection may be described in terms of the following equation:

$$P = \frac{C - E}{C} \times 100,$$

where P is the degree of protection in per cent, C the control drop in vital capacity produced by administration of the bronchospastic substance (before the protecting drug is given), and E the drop similarly produced at any time after the protecting agent has been administered. These percentage values may then be massed into averages derived from several experiments on different asthmatic subjects. Determination of such averages is necessary, for we have repeatedly encountered single protection studies, or even repeated studies in the same individual, which were at variance with the average of results obtained by employing the same drugs in many experiments carried out on many individuals.

RESULTS

1. *Epinephrine hydrochloride.* Epinephrine hydrochloride 1:1000, 0.5 cc. subcutaneously, cause the usual side-reactions of throbbing in the chest and head, uneasiness, tremor, etc. Protection was striking, however, in that this dose afforded 100 per cent "immediate" (five to ten minutes after injection) protection against intravenous histamine. This decreased gradually reaching a level of 40 per cent after 143 minutes (Figure 1). This 40 per cent level has previously (9) been proposed as the minimum at which protection may be considered significant, in view of the errors inherent in any technique of clinical assay. Against the bronchospastic effects of methacholine, epinephrine hydrochloride 1:1000, 0.5 cc. subcutaneously, provided 90 per cent immediate protection and maintained a significant level, over 40 per cent, for 83 minutes. These results are presented in tabular form in Table II.

Subcutaneously administered epinephrine was also assayed against the bronchospastic effect of aerosols of histamine and methacholine and dis-

EPINEPHRINE	OH	OH	H	OH	H	CH ₃
VAPONEFRIN	OH	OH	H	OH	H	CH ₃
ISUPREL	OH	OH	H	OH	H	HC(CH ₃) ₂
EPHEDRINE	H	H	H	OH	CH ₃	CH ₃
ORTHOXINE	H	H	OCH ₃	H	CH ₃	CH ₃

Vaponefrin is a specially prepared racemic epinephrine.

played somewhat less, though still very effective protecting ability. Against histamine it showed 70 per cent immediate protection, which rose to a peak of 86 per cent at 40 minutes, and maintained a level greater than 40 per cent for 127 minutes. Less protection against methacholine was again observed; there was an immediate level of 40 per cent, rising to a peak of 51 per cent at 38 minutes, and remaining at a significant level for 72 minutes.

The 1:100 dilution of epinephrine hydrochloride (10) was dispensed in a glycerine-water solution, as were all other agents employed as aerosolized mists. Deep inhalations at ten-second intervals

were administered with a standard Vaponefrin hand-bulb nebulizer until six were completed. Against intravenous histamine 75 per cent immediate protection was observed. The significant level of 40 per cent lasted for 28 minutes. Against intravenous methacholine there was 56 per cent immediate protection and an 18 minute duration of the 40 per cent level (Figure 2).

The protective capacity of epinephrine aerosol appeared slightly greater when assayed against nebulized bronchospastic agents. There was 89 per cent immediate protection and 36-minute duration of the 40 per cent level against histamine;

and 66 per cent immediate and 17-minute duration of the 40 per cent level against methacholine. These data are not, however, significantly different from those obtained with the intravenous bronchospastics.

2. *Vaponefrin*.⁸ This is a 2.25 per cent solution of a specially prepared synthetic racemic epinephrine. Richards, Barach and Cromwell (11) considered it preferable to the official 1:100 solution of epinephrine hydrochloride, which is the levo-rotatory isomer. We have compared these aerosols elsewhere (12).

Using histamine intravenously we found that six deep inhalations of Vaponefrin aerosol provided 93 per cent immediate protection and significant protection (over 40 per cent) lasting 27 minutes. Against intravenous methacholine we obtained an immediate level of 74 per cent and a duration of a significant level of 18 minutes. Employing the bronchospastics by nebulization resulted in no greatly significant difference in intensity of action, 90 per cent against histamine and 87 per cent against methacholine. However, the 40 per cent level was maintained definitely longer, 53 minutes with histamine and 40 minutes with methacholine (Figure 2). The explanation for this discrepancy is obscure; it may simply be due to inadequate sampling.

3. *Neosynephrin*. As may be seen from Table I, this drug differs from epinephrine only in the absence of the para-hydroxyl group on the aromatic portion of the molecule. The compounds resulting from removal of one or both hydroxyl groups are more stable but have greatly decreased inhibitory effects. Various investigators (11, 13-15) have found neosynephrin of little value as a bronchodilator although it may be an efficient bronchovasoconstrictor (14, 15).

Utilizing the 1:100 solution of neosynephrin, we have studied the protecting effect of the drug administered by nebulizer and by hypodermic injection. Our studies were limited to intravenous use of the bronchospastic agents. Figure 1 portrays the ineffectiveness of 0.3 cc. subcutaneously, the level of protection never exceeding 20 per cent. Neosynephrin aerosol, 1:100, in the usual dose of six deep inhalations, proved somewhat more effective (Figure 2), displaying against histamine 52 per cent immediate protection which dropped below 40 per cent within 16 minutes. Against methacholine no significant protective levels were attained, 32 per cent being the highest observed.

4. *Isuprel*.⁹ This sympathomimetic amine, 1-(3,4-dihydroxyphenyl)-2-isopropylaminoethanol differs from epinephrine only in the alkyl group

⁸ Kindly supplied by the Vaponefrin Co., Upper Darby, Pennsylvania.

⁹ Kindly supplied by Winthrop-Stearns, Inc., New York, New York.

FIG. 2. THE PROTECTION NOTED AGAINST HISTAMINE AND METHACHOLINE (REFERRED TO ABOVE AS MECHOLYL) BY NEBULIZED SOLUTIONS OF EPINEPHRINE HYDROCHLORIDE (1:100), VAPONEFRIN (2.25 PER CENT) AND NEOSYNEPHRIN (1 PER CENT)

attached to the nitrogen atom (Table I). It has been demonstrated that substitution on the amino nitrogen of branched alkyl groups, particularly isopropyl (as in Isuprel) and *tert*butyl, produces compounds with enhanced sympathin I-mimetic properties (4-7, 16). The specific structure of the substituted alkyl group is also important in influencing the inhibitory potency of such compounds.

The clinical efficacy of Isuprel has been previously reviewed by Segal and Beakey (17, 18), who introduced its use in this country. Cohen and Van Bergen (19) have found Isuprel a most effective antagonist of methacholine-induced bronchospasm in animals and of spontaneous asthma in man.

We have employed a 1:50,000 dilution of Isuprel intravenously in a few subjects with variable results. Occasionally the most dramatic possible complete relief of clinical asthma has been noted, while a dose of 0.25 cc. (0.005 mgm.) was still being administered. The effect persisted for a matter of hours. In other instances relief was only partial and transient after intravenous administration of 0.25 cc. (0.005 mgm.) to 0.5 cc. (0.01 mgm.), even in repeated doses. The 0.25 cc. dose caused a uniform increase of 20-30 beats per minute in the heart rate. All patients experienced unpleasant, although not alarming, palpitations. The 0.5 cc. dose, on the other hand, accelerated the pulse by 50 beats per minute and caused uneasiness and alarming palpitations. The

effect on blood pressure was minimal. The dose of 0.005 mgm. appeared to cause a small increase in systolic pressure (approximately 10 mm. of mercury), probably due mainly to the increased rate. There appeared to be, in general, a tendency toward a slight fall in the diastolic level. The larger dose, 0.01 mgm. (0.5 cc.), caused a transient drop in systolic and diastolic levels simultaneous with the greatest increase in heart rate. We performed several protection studies using this very dilute solution of Isuprel intravenously. Doses of 0.25 cc. (0.005 mgm.) and 0.5 cc. (0.01 mgm.) failed to demonstrate any protective ability against histamine or methacholine for long enough periods to be measured by the method employed.

Isuprel 1:100, the dilution commonly employed

with epinephrine, provided essentially complete immediate protection against intravenous histamine and methacholine (98 and 91 per cent respectively). Not only did it maintain a significant (40 per cent) protection against histamine for 62 minutes, but it also afforded a surprising 81-minute duration against methacholine (Figure 3). However, this dilution of Isuprel frequently caused unpleasant epinephrine-like side-effects.

Isuprel 1:200 is the dilution in common use for nebulization. It is, of course, one-half as concentrated as the usual epinephrine solution and equivalent to approximately one-third the concentration of levo-epinephrine in Vaponefrin. This dilution of Isuprel displayed (Figure 3) 70 per cent immediate protection against intravenous histamine with a duration of 22 minutes for

FIG. 3. THE PROTECTIVE CAPACITY OF ISUPREL ADMINISTERED BY VARIED ROUTES AND IN VARIED AMOUNTS AGAINST HISTAMINE AND METHACHOLINE (REFERRED TO ABOVE AS MECHOLYL)

significant levels. Against intravenous methacholine, there was a 69 per cent immediate level and significant levels persisted for 42 minutes. As may be seen in Table II, the data were, with one exception, essentially equivalent when the bronchospastics were employed in the form of aerosols. An immediate level of 84 per cent and a 21-minute duration of significant protection were found against histamine; and 65 per cent with 25 minutes were the comparable values for methacholine. The only discrepancy appears in the duration of levels over 40 per cent against methacholine administered intravenously and as an aerosol. This, again, may be due to inadequate sampling and the consequent chance inclusion of patients with extreme differences in responsiveness to Isuprel.

An average dose of the 1:5000 dilution of Isuprel for subcutaneous injection is 0.5 cc. This dose was assayed against intravenous histamine and methacholine (Figure 3). We obtained complete (100 per cent) immediate protection against histamine and a continuation of significant levels for 30 minutes. Less anticholinergic effect was noted with this preparation, for the initial intensity was only 56 per cent, and it dropped to 40 per cent in 18 minutes.

Sublingual tablets of Isuprel, although they have been moderately effective clinically in occasional patients, have not proved to be an adequate substitute for a nebulizer in most cases. We have performed protection studies with these tablets in doses of 20 mgm. (two tablets) against histamine and methacholine administered intravenously. Against histamine, significant levels of protection were not attained, and a peak of 38 per cent was reached in 27 minutes. Against methacholine the results were very similar although the 40 per cent level was reached in 12 minutes after the tablets dissolved under the tongue. (Time for dissolution was usually two to three minutes.) The total duration of levels over 40 per cent was 23 minutes. However, the peak level, attained 24 minutes after dissolution of the tablets, was only 44 per cent. These data are presented graphically in Figure 3.

5. *Ephedrine*. From Table I it may be seen that ephedrine is lacking in the hydroxyl groups on the benzene ring, and possesses an additional methyl group attached to the alpha-carbon atom.

Clinically it has longer, less intense action than epinephrine; it is active orally.

In our studies, employing the usual oral dose of 25 mgm. (administered several hours after the subject's last meal), there was a delay of 81 minutes before a protection level of 40 per cent was reached against histamine (Figure 4). A peak level of 57 per cent was attained at 120 minutes. Significant levels of 40 per cent or over were maintained for 108 minutes, or until slightly over three hours after the drug was taken. Against methacholine, no significant levels of protection were reached. The peak level was only 32 per cent, occurring 60 minutes after ingestion of the therapeutic agent.

FIG. 4. THE PROTECTING ABILITY OF ORALLY ADMINISTERED EPHEDRINE SULFATE (25 MGM.) AND ORTHOXINE (200 MGM.) AGAINST HISTAMINE AND METHACHOLINE (REFERRED TO ABOVE AS MECHOLYL)

6. *Orthoxine*.¹⁰ This synthetic amine differs from ephedrine in the absence of the beta-hydroxyl group and the presence of a methoxy radical in the ortho position.

We have made a clinical trial in approximately 20 patients with a dose of 100-200 mgm. three to four times daily. In general it proved to be of little benefit in preventing severe asthmatic attacks, although one patient obtained moderate relief and one noted marked improvement. Side-effects were observed by many patients and varied among anorexia, nausea, light-headedness, dizziness and drowsiness. Only one patient complained of the ephedrine-like effect of insomnia. The syrup of orthoxine has been tolerated fairly well and appears to give clinical relief from troublesome cough in some patients.

In protection studies against intravenous histamine, orthoxine, in a dose of 200 mgm. orally, was apparently rapidly absorbed, for it displayed 49 per cent protection at 57 minutes. In addition, this proved to be the peak level attained inasmuch as the protective capacity dropped very gradually to 40 per cent at 165 minutes after ingestion of the drug. The total measured duration of significant protection was 108 minutes. Against methacholine, a 40 per cent level was never reached. The peak attained was 38 per cent at 120 minutes. These figures for orthoxine, graphically presented in Figure 4, obviously are very closely similar to those for ephedrine.

SUMMARY AND CONCLUSIONS

1. Five well-known sympathomimetic amines and one new one have been studied with respect to their protective capacity against the bronchospastic effects of histamine and methacholine in sensitive asthmatic patients.

2. No consistent difference in results was observed whether the bronchospastic agents were administered intravenously or as aerosols.

3. Epinephrine hydrochloride 1:1000, 0.5 cc. subcutaneously, protected as well as or better than the other agents tested and afforded greater duration of significant protection. However, its cardiovascular and central nervous stimulating side-effects proved disagreeable.

4. *Orthoxine* supplied by The Upjohn Co., Kalamazoo, Michigan

4. Isuprel 1:100 aerosol (double the usual strength), six inhalations, was comparable to the subcutaneously administered epinephrine, particularly in anticholinergic effect, although it protected less than half as long against histamine. This, too, caused undesirable side-effects.

5. Of the three most commonly employed solutions for nebulization, Vaponefrin, 2.25 per cent, appeared to have a slightly greater antihistaminic protecting ability than Isuprel 1:200 and epinephrine 1:100. The latter two were of approximately equal efficacy as antihistaminics. Isuprel 1:200 demonstrates greater anticholinergic protecting ability than either of the other two preparations.

6. Neosynephrin was quite ineffective when injected parenterally and of only slight value by the inhalatory route.

7. Sublingually administered Isuprel, in a dose of 20 mgm., proved to have little protective capacity against the bronchospastic effects of histamine and methacholine. It was occasionally of moderate value clinically when administered by this route.

8. Isuprel 1:5000, 0.5 cc. subcutaneously, displayed excellent though brief protecting ability against the bronchospastic effects of histamine and considerably less effectiveness against methacholine.

9. Isuprel 1:50,000 could not, because of cardiovascular side-effects, be injected intravenously in doses sufficient to effect measurable protection. Doses of 0.25 cc. and 0.5 cc. (0.005 to 0.01 mgm.) occasionally proved dramatically effective in alleviating clinical asthma, although it usually was less effective and quite transiently so.

10. A new sympathomimetic amine, orthomethoxy-beta-phenylisopropyl methylamine hydrochloride (*Orthoxine*, Upjohn), of the class of ephedrine, was studied and appeared quite similar to the latter in protecting capacity. Brief clinical trial indicated that the ortho-methoxy group may occasionally reverse the central stimulation of ephedrine.

ACKNOWLEDGMENT

We are indebted to Dr. H. J. Rubitsky for carrying out several protection study tests in this series.

EVALUATION OF THERAPEUTIC SUBSTANCES EMPLOYED FOR THE RELIEF OF BRONCHOSPASM. VI. AMINOPHYLLINE¹

By MAURICE S. SEGAL,² LEON LEVINSON,³ ELLIOTT BRESNICK,⁴
AND JOHN F. BEAKEY⁵

(From the Department of Inhalational Therapy, Boston City Hospital, and the Department of Medicine, Tufts College Medical School, Boston, Mass.)

(Received for publication March 31, 1949)

The use of various xanthine derivatives in the management of bronchial asthma was first described by Herrmann and Aynesworth (1) in 1937. They were able to demonstrate definite increases in the vital capacity of patients with bronchial asthma after the intravenous administration of aminophylline. The clinical contributions of Barach (2), Cooke (3), Unger (4), Segal (5) and others amply describe the valuable role played by this medication in the management of patients seriously ill with bronchial asthma.

We have previously described in detail (6-10) the historical development of a technique for evaluation of medications employed in the treatment of bronchial asthma by testing the efficacy of such compounds in preventing the decrease in vital capacity artificially induced in sensitive asthmatic subjects by the administration of suitable bronchospastic agents (histamine, methacholine, or allergens). The exact relationship of the dyspnea and bronchospasm induced by histamine or by methacholine to that occurring in spontaneous bronchial asthma is uncertain. However, since it is probable that only asthmatic or potentially asthmatic individuals respond to these agents by changes in vital capacity (7, 11, 12), this technique of assay in man may be of value. This report will concern itself with the results obtained with theophylline-ethylene diamine (Aminophylline, U.S.P.).

METHODS

A protection study consists of the observation of the decreases in vital capacity produced by the repeated ad-

ministration of a bronchospastic agent (by any of various routes) before and after a protecting drug is administered. A "control" drop, which should be equal to at least one-quarter of the resting vital capacity, is first established; this drop should preferably exceed 1000 cc. The protecting agent is then administered (by any of various routes) and bronchospasm re-induced at suitable intervals until the effect of the protecting agent disappears. We have devised an equation (1, 2) by which the degree of protection afforded by any given drug at any time may be expressed in percentage:

$$P = \frac{C - E}{C} \times 100,$$

where P represents the degree of protection in percentage, C equals the control drop in vital capacity before the protecting drug is given, and E is the drop produced at any time after the protecting drug has been administered. These data, being independent of vital capacity determinations, may be grouped into averages. Since we have repeatedly encountered individual protection studies which vary greatly from the mean derived from a group of studies, we have computed all our data on the basis of such averages derived from at least four individual protection studies on different subjects.

RESULTS

By means of this technique we have measured the protecting ability of aminophylline, administered by various routes, against the decrease in vital capacity induced by the intravenous or aerosol administration of histamine or of methacholine.

(1) *Intravenous aminophylline vs. intravenous histamine and methacholine.* After the intravenous injection of 0.5 Gm. of aminophylline in 20 cc. of distilled water, over a period of ten minutes, protection against the bronchospastic effects of histamine⁶ and of methacholine⁷ was observed immediately. Against histamine, this immediate level was 65 per cent; against methacholine it was only 37 per cent. In view of the many unavoidable

⁷ The preparation used ("mecholy" chloride) was kindly supplied by Merck and Co., Rahway, New Jersey.

errors inherent in any technique of clinical assay, we have considered all protection values below 40 per cent as insignificant. With this figure as a standard, it is apparent that intravenous amino-

phylline displays a protecting action against methacholine which is just short of being significant. Significant protection against intravenous histamine persisted for two hours and ten minutes

COMPARATIVE PROTECTIVE VALUE OF AMINOPHYLLINE ADMINISTERED BY VARIOUS ROUTES AGAINST HISTAMINE AND MECHOLYL-INDUCED DYSPNEA AND BRONCHOSPASM IN ASTHMATIC SUBJECTS.

* AMINOPHYLLINE AEROSOL ALSO EXHIBITED NO SIGNIFICANT PROTECTION AGAINST THE EFFECTS OF HISTAMINE AND MECHOLYL AEROSOLS

(Figure 1, Table I). The lesser degree of protection displayed against the effects of intravenous methacholine was of shorter duration as well.

(2) *Intramuscular aminophylline vs. intravenous histamine and methacholine.* Administration of 0.5 Gm. of aminophylline in 2 cc. of distilled water intramuscularly in the gluteal region led to protection against the decrease in vital capacity induced by the intravenous administration of histamine and methacholine which never quite achieved significant levels (Figure 1, Table I). In this case, as in the case of intravenous aminophylline and methacholine, the maximum protecting levels were just below our arbitrary level of significance, being 36 per cent in the case of intramuscular aminophylline against histamine, and 38 per cent against methacholine. These peak levels were reached after a considerable delay (50 minutes for histamine, 90 minutes for methacholine) and were maintained for comparatively brief intervals.

(3) *Rectal solution of aminophylline vs. histamine and methacholine.* A solution of aminophylline containing 0.5 Gm. in 15 cc. of distilled water was instilled rectally by means of a Dakin syringe and a well-lubricated No. 12 Fr. urethral catheter. Aminophylline so administered resulted in significant protection (above 40 per cent) against the bronchospastic effects of intravenous histamine for two and one-half hours and against intravenous methacholine for one and one-half hours. This occurred after delays of 45 and 55 minutes respectively, presumably incident to absorption. After the rectal administration of 0.5

Gm. of aminophylline, a peak level of 58 per cent protection against histamine was attained in two hours; 45 per cent protection against methacholine was attained in one and three-quarters hours (Figure 1 and Table I).

(4) *Oral aminophylline vs. intravenous histamine and methacholine.* Orally administered aminophylline in the form of two compressed tablets of 0.2 Gm. each yielded protection to a lesser degree against the decrease in vital capacity produced by subsequently administered intravenous histamine and methacholine. Barely significant peak values of 45 and 42 per cent against histamine and methacholine respectively were obtained (Figure 1 and Table I). Significant protection (40 per cent) was attained only after a delay of one and three-quarters hours in the case of histamine, and two hours and ten minutes in the case of methacholine. With histamine, the duration of significant protection was only 50 minutes; with methacholine, 20 minutes.

(5) *Aerosol aminophylline vs. aerosol and intravenous histamine and methacholine.* The relative ease of aerosol administration of small quantities of concentrated solutions of adrenergic agents has led us to investigate the properties of an aerosol produced with the standard Vaponefrin nebulizer from a 25 per cent solution of aminophylline. The disagreeable taste of this preparation may be partially masked by the addition of a drop or two of spirits of peppermint. We first investigated the protecting action of six inhalations of such a mist, produced with hand-bulb nebulization, but

were unable to demonstrate any protecting action against the bronchospastic effects of subsequently administered histamine or methacholine, the latter being given both intravenously and as an aerosol. We then nebulized 0.25 Gm. of aminophylline in 1.0 cc. of distilled water employing the Vaponefrin nebulizer with oxygen flows, using the intermittent Y-tube occlusion technique. This procedure is time-consuming and the aerosol is irritating to the pharynx and trachea. No significant protection could be demonstrated (Figure 1 and Table I). Peak protection values in all instances reached only 12 to 17 per cent.

(6) *Direct comparison of various routes.* The striking disparity in protection obtained after the administration of aminophylline via various routes led us to compare the antihistaminic potency of aminophylline in each of the five routes employed. In two subjects, R. L. and J. S., aminophylline was administered on successive visits to the laboratory via each of the five routes employed, so that a more direct comparison between these methods of administration might be made (Figure 2). It is apparent from these curves that in both cases optimum antihistaminic activity appeared after the rectal administration of a solution containing 0.5 Gm. of aminophylline. In these two individuals intravenous and intramuscular administration were of essentially equal activity; the intravenous route, however, has the advantage of immediate

action. Orally administered aminophylline in a slightly smaller dose was definitely less effective than intravenous or intramuscular medication. Aerosol aminophylline was, as previously noted, totally ineffective.

DISCUSSION

In contrast to the data obtained by similar examination of the protecting ability of various adrenergic agents (10) against the decrease in vital capacity produced by intravenous injections of histamine and methacholine, it is apparent that aminophylline must exert its bronchospasmolytic action in a different manner. Such anti-asthmatic drugs as the sympathomimetic amines have a rapid, intense protecting action in minute doses, whereas the effect of aminophylline is milder and more prolonged and the dose employed is many times greater. In dosage and in the time sequence of its protecting action, aminophylline approaches more closely the antihistaminic drugs (blocking agents), data on which will be presented elsewhere (13).

The administration of aminophylline solution by rectum has been extensively popularized in recent years (2). We have long been aware of the powerful bronchospasmolytic action of such medication in the management of patients with severe asthma. This impression is amply borne out by these studies, in which rectally administered

FIG. 2. THE COMPARATIVE PROTECTING ACTION OF AMINOPHYLLINE ADMINISTERED BY EACH OF FIVE ROUTES TO TWO ASTHMATIC PATIENTS AGAINST THE DYSPNEA AND BRONCHOSPASM PRODUCED BY HISTAMINE AND METHACHOLINE (REFERRED TO ABOVE AS MECHOLYL)

aminophylline exhibits a protecting action equal or superior to all other routes, if the 45 to 60 minute absorption delay time is not objectionable. As absorption after oral administration is slower and as the period of significant protection is shorter, this route can have only limited value. Intramuscular aminophylline made a poor showing, one not entirely unexpected in the light of clinical experience. Were the pain usually attendant upon such an injection not already a sufficient deterrent to its clinical use, the lack of significant protecting ability should discourage dependence upon this route. It is our feeling that rectally administered aminophylline solution affords the patient a potent means for relief of asthmatic bronchospasm; moreover, the ease of self-administration of the rectal solution is, of course, an even more important factor. Where maximal immediate effect is essential, the intravenous administration remains the route of choice.

SUMMARY

1. The protecting ability of aminophylline, administered by various routes, against the dyspnea and bronchospasm produced by the administration of histamine and methacholine by various routes is presented.

2. The intravenous administration of 0.5 Gm. of aminophylline results in immediate protection against the bronchospastic effects of histamine and methacholine; the protection against histamine, which is definitely of significant degree, persists for two hours and ten minutes. Protection against methacholine falls below an arbitrary limit of significance.

3. Rectal administration of a solution of 0.5 Gm. of aminophylline yields a degree of protection against the dyspnea and bronchospasm produced by intravenous histamine and methacholine equal or superior to that produced by intravenous injection of the same dose of the drug. There is a 45 to 60 minute delay incident to absorption from the rectal mucosa, whereas the effects of the drug are apparent immediately following intravenous injection.

4. Aminophylline given intramuscularly (0.5 Gm.) is relatively ineffective in counteracting the bronchospastic effects of intravenous histamine and methacholine.

5. The oral administration of 0.4 Gm. of aminophylline results in relatively low degrees of protection as compared to that obtained with the rectal route. Significant protection appears only after a long delay and persists for an extremely short period of time.

6. Aminophylline in the form of an aerosol mist is almost totally ineffective in preventing the dyspnea and bronchospasm produced by intravenous or aerosol administration of histamine or of methacholine.

ACKNOWLEDGMENT

We are indebted to Dr. H. J. Rubitsky for carrying out several protection study tests in this series.

CHLORAMPHENICOL (CHLOROMYCETIN) IN THE TREATMENT OF TSUTSUGAMUSHI DISEASE (SCRUB TYPHUS)

By JOSEPH E. SMADEL, THEODORE E. WOODWARD, HERBERT L. LEY, JR.,
AND RAYMOND LEWTHWAITE

(From the Army Medical Department Research and Graduate School, and the Commission on Immunization of the Army Epidemiological Board, Washington, D. C.; the University of Maryland School of Medicine, Baltimore; and the Institute for Medical Research, Kuala Lumpur)

(Received for publication May 3, 1949)

The present paper augments information previously published on the first 25 patients with scrub typhus to receive chloromycetin (1) and reviews our experience in the use of this drug in the treatment of a total of 69 persons who contracted tsutsugamushi disease in the vicinity of Kuala Lumpur, Federation of Malaya. The results obtained in this group are compared with those observed in 19 patients with the disease who received only supportive therapy and in three who were given p-aminobenzoic acid.

MATERIALS AND METHODS

Chloromycetin. Chloromycetin¹ prepared by the fermentation process was supplied for the current work by Parke, Davis and Company. A small amount of the antibiotic, subsequently administered in capsules, was received as pure crystalline material but almost all of the drug was in the form of tablets containing 0.25 gm. amounts of active crystalline material. All treatment was by the oral route.

The levels of chloromycetin in the serum and other body fluids were determined by a modification (2) of the technique described by members of the Research Laboratories of Parke, Davis and Company (3). This is a turbidimetric bioassay method in which the amount of drug in a known standard required to produce 50 per cent inhibition of growth of *Shigella paradysenteriae* (Sonne)² is compared with the inhibiting capacity of varying dilutions of the unknown material.

Isolation of rickettsiae. The presence of rickettsemia in patients was demonstrated in the following manner. Freshly drawn blood was defibrinated, by shaking with glass beads, and centrifuged; the plasma was discarded and the sedimented red cells were resuspended in an equal volume of physiological saline solution. One-half cc. of such a suspension was injected intraperitoneally

into each of four normal young adult albino mice of one of several inbred lines. Mice inoculated with blood containing rickettsiae generally showed signs of illness between the ninth and 12th days, and died between the 11th and the 14th. With few exceptions, the rickettsial strains recovered in the vicinity of Kuala Lumpur were highly virulent for mice, and usually all of the animals which received the infected blood died unless sacrificed for study. One mouse from the original group was sacrificed when it first showed signs of illness or on the 12th day. When the results were positive, these animals displayed the typical gross pathological changes of experimental *Rickettsia tsutsugamushi* infection in mice, i.e., enlargement of lymph nodes and injection of vessels observed when the ventral skin was reflected, sero-gelatinous peritoneal exudate, enlargement of the spleen, and accumulations of pleural fluid. Impression smears from the surface of the spleen and scrapings from the peritoneal surface of the abdominal wall, when stained by Giemsa's method, contained intracellular rickettsia-like organisms. The presence of such macroscopic lesions and the finding of rickettsiae microscopically were considered presumptive evidence of *R. tsutsugamushi* infection. Almost without exception rickettsiae were demonstrated microscopically in at least two of the four mice originally injected with the patient's blood. Furthermore, in the majority of instances a splenic suspension of material, or peritoneal exudate, from a mouse of the original group was passed by intraperitoneal injection to a second group of four normal animals in which the disease picture was reproduced. On a number of occasions the agent was maintained for several months by serial passages in mice. The strain obtained from treated Patient 9 was used as challenge material to demonstrate the immunity of occasional mice convalescent from infections with other strains and to determine whether mice had had inapparent infection following inoculation with a patient's blood. Seven of the strains were brought to the Army Medical Department Research and Graduate School where they were shown by reciprocal cross-immunity tests to be related to the well known Karp strain of *R. tsutsugamushi*. It was our experience that the attempted isolation of rickettsiae from blood of patients generally gave clean-cut results in the original mice. Thus, the employment of the blind passage technique and the testing of surviving mice for immunity by challenge with known lethal amounts of rickettsiae

¹Chloramphenicol is now the generic name for the antibiotic originally designated chloromycetin. Chloromycetin has been reserved as a trade name by Parke, Davis and Company.

²This organism is now classified by Bergey (1948) as *Shigella sonnei*.

rarely yielded indications of rickettsemia in the patient unless the original mice had shown obvious disease. It may be noted that strains of *R. tsutsugamushi* found in different geographical areas vary considerably in their pathogenicity for mice (4). Therefore, it was fortuitous and fortunate that the Malayan strains were relatively easy to recover and identify.

Serological tests. Weil-Felix tests were performed using standardized suspensions of OX-K and OX-19 strains of *Bacillus proteus* according to the technique of the Army Medical Department Research and Graduate School (5) or that of the Institute for Medical Research. Specific complement-fixation tests employing the washed rickettsial antigens of *R. prowazeki* and *R. mooseri* (6) were done in selected instances. Similarly, agglutination tests for *Leptospira icterohemorrhagiae* were performed on specimens from certain patients by the Veterinary Division of the School.

Routine clinical laboratory procedures. Erythrocyte and leukocyte counts and differential white blood cell counts were made in the usual manner. Hemoglobin values were determined spectrophotometrically by the cyanomethemoglobin method (7) and the usual procedures were employed for urinalysis. Blood levels of para-aminobenzoic acid were determined by a colorimetric procedure (8).

RESULTS

Patients with scrub typhus acquired during normal occupational duties

Selection of patients. Thirty patients who acquired scrub typhus during normal occupational duties were treated with chloromycetin. Twenty-eight of these contracted their disease in the vicinity of Kuala Lumpur. Twelve of the group became infected while working at the Seaport Estate between Kuala Lumpur and Batu Tiga (see Figure 1). The air field on the outskirts of Kuala Lumpur provided four of the cases who were treated. The remaining 12 occurred singly or in small groups within a 20 mile radius of the Institute for Medical Research. Patient 9 contracted his infection in Singapore and Patient 49 acquired hers following an accident at the Army Medical Department Research and Graduate School while handling the strain from treated Patient 25.

The course of the disease in patients who were given only supportive treatment was recorded in 19 persons who were observed during the period of the study. All of these acquired their infection in the general area which supplied the majority of the patients who received chloromycetin and five of them became infected on Seaport Estate. These

untreated patients were observed during periods when a supply of the specific antibiotic was not available, or the drug was withheld because they were first seen late in the disease and were not then desperately ill.

No effort was made to restrict the administration of chloromycetin to alternate patients who came under study. A precise balance could not have been obtained in this relatively limited investigation by selecting alternate patients for treatment unless certain important factors were evenly distributed in the treated and control groups; a few of these factors were age, sex, race, history of previous exposure in infected areas, and the virulence of the infecting strain of *R. tsutsugamushi*. Nevertheless, many of these variables were eliminated in the group of 17 patients from Seaport Estate in which five served as untreated controls. Early in the work it became quite clear that the course of the disease in the treated patients was markedly different from that observed in untreated persons in the current group or in patients with scrub typhus who had been studied during the preceding 20 years by members of the Institute for Medical Research (9-11). This marked difference in response of treated and untreated patients greatly simplified the interpretation of results.

Observations on patients with scrub typhus given supportive treatment. Detailed data on the 19 cases of scrub typhus who did not receive specific therapy are given in Table I. The more pertinent information is summarized in Table II. As the tabular data indicate, the average duration of fever in this group of persons was 17.1 days with extremes of 12 and 31. The course of the disease was complicated in two of the 19 patients by pneumonia and one of them died as a result. A third patient had suppurative parotitis which required surgical intervention.

All of these untreated patients were diagnosed on the basis of the history, clinical findings, and a positive Weil-Felix reaction. The diagnosis was further established in untreated Patient 16 by recovery of *R. tsutsugamushi* from the patient's blood.

Observations on patients with scrub typhus treated with chloromycetin. Information on each of the 30 treated patients and a summary of certain of the data are given in Tables II and III, respectively. The response following administra-

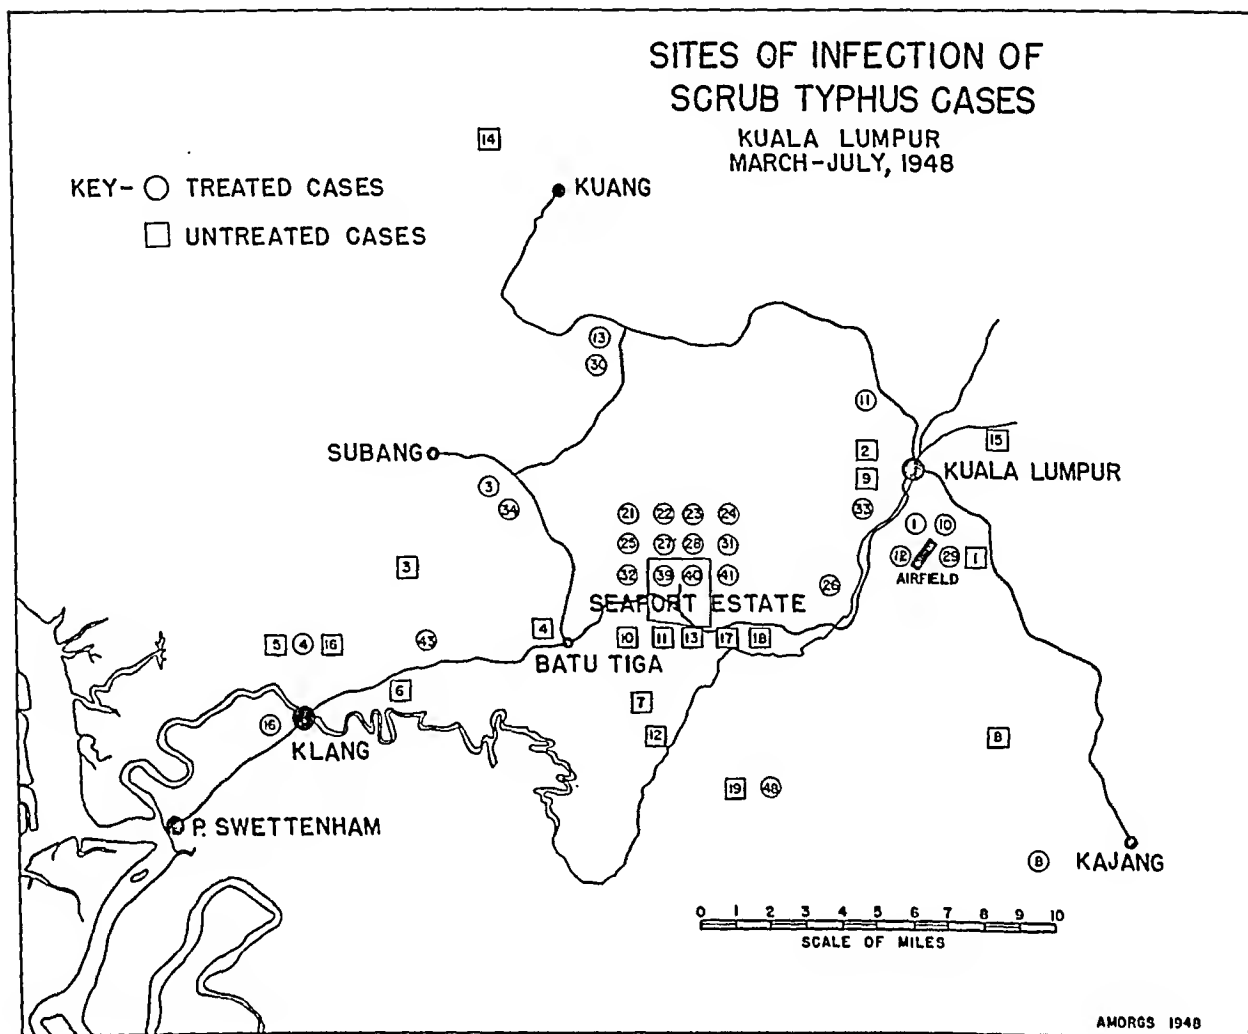

FIG. 1

tion of chloromycetin has been so consistent that it will be sufficient to present certain illustrative cases and to draw general conclusions.

All cases were given an initial oral dose of chloromycetin of about 60 mg./kg. of body weight. Since most of the patients were of small stature and weighed from 50–60 kg., this initial dose was usually between 3.0 and 3.5 gms. Following this dose, the patients were maintained for a variable period of time on 0.25 gm. amounts of drug administered at intervals of three hours. For example, treated Patient 1, whose clinical record is graphically presented in Figure 2, followed this regime for 48 hours and was then maintained on drug in reduced amounts for the three succeeding days. This patient who was started on chloromycetin on the fifth day became afebrile within 20 hours and remained free of fever thereafter. As therapeutic experience increased the total amounts of drug and the duration of therapy were

reduced (see Table III). Treated Patient 29, whose record is illustrated in Figure 3, was started on specific therapy on the sixth day and received a total of 6.5 gms. over a period of 22 hours. He became afebrile within 24 hours after the initial dose. A short course of drug such as used for Patient 29 provided results which appeared to be as satisfactory as those obtained when larger amounts were given over a period of four or five days.

The clinical diagnosis of scrub typhus was confirmed in each of the 30 patients by demonstration of rickettsemia or the development of a positive Weil-Felix reaction (see Table III). Rickettsiae were isolated from the bloods of 26 of the 30 patients. At least a four-fold increase in titer of agglutinins for the OX-K strain of *B. proteus* was shown to develop during convalescence in 28 of the patients. Convalescent sera from treated cases Nos. 12 and 24 had OX-K agglutinins in low titer

A total of 11.6 gms. of chloramphenicol was given over a period of 120 hours.

but did not contain a significant increase over the acute phase sample. The diagnosis was established, however, in each of these patients by the isolation of *R. tsutsugamushi*.

A comparison of the results obtained in the treated and untreated groups of patients is given in Table II. In the treated cases recovery began within a matter of hours after specific therapy was instituted, and fever lasted from six to 96 hours after chloromycetin was begun; the average duration being 31.8 hours for the entire group of 30 patients. It may be mentioned that treated Pa-

tient 9, who required 96 hours to become afebrile, was irrational, cyanotic and *in extremis* when treatment was started late on the ninth day. Although defervescence was slow this patient began to improve clinically within 12 hours after the antibiotic was administered, for at that time he sat up in bed and complained because breakfast was inadequate. It is worthy of note that chloromycetin therapy was equally effective whether given early or late in the disease. Thus, treated Patients 28 and 31, who were first seen on the third day, required 36 hours to become afebrile

FIG. 4. CLINICAL RESPONSE OF PATIENT CP 14 TO CHLOROMYCETIN THERAPY BEGUN ON THE THIRD DAY OF DISEASE

He relapsed on three occasions, each recurrence responded promptly to additional treatment with chloromycetin.

while treated Patient 13, who was given the antibiotic on the 11th day, became afebrile within 24 hours. The average day on which therapy was begun for the treated group was 6.2 and the last febrile day of the illness was 7.4. This may be compared with that of the last febrile day of illness in the untreated group; this varied between 12 and 31 and averaged 17.1 days.

The first treated patient, although afebrile on the sixth day after onset, was kept in the Military Hospital until the 28th day. As additional patients were added to the series the period of hospitalization steadily diminished from four weeks to about two weeks (see Table III). The average for the entire group was 17.8 days,³ which con-

trasts with an average hospitalization of 29.9 days in the untreated group. There were no complications and no deaths among the treated patients whereas among the untreated persons one died and two others had serious complications.

Patients with other diseases who received chloromycetin

The cases of suspected scrub typhus destined for specific therapy were numbered serially as they came under observation. It is apparent from Table III that the 30 patients with scrub typhus were culled from a series of 49 persons who were originally thought to have tsutsugamushi disease. Treated Patients 44 and 45 who are listed in

³ Treated patients were generally up and about in the hospital and grounds within a few days after becoming afebrile but they were kept in the hospital, although ap-

parently fully recovered, in order to permit medical observation and to prevent their returning to occupational duties.

Table IV suffered from scrub typhus but because of the circumstances surrounding the acquisition of their disease they are not included in the present group. Treated Patients 46 and 47, Gurkah soldiers who acquired scrub typhus during jungle fighting, are reported in detail elsewhere (12) and will not be included in this group. These were the first two persons to receive the synthetic form of chloromycetin. Among the remaining 15 cases who were treated with chloromycetin, two (Nos. 18 and 19) had typhoid fever (13) and three (Nos. 6, 7, and 35) had murine typhus (14), two (Nos. 36 and 42) were infected with *Leptospira icterohemorrhagiae*, and one (No. 37) had malarial hematuria (blackwater fever). No definitive diagnosis was established for the remaining seven patients (Nos. 2, 5, 14, 15, 17, 20, and 38) but all recovered promptly; the contribution of chloromycetin to their recovery could not be assessed. The efficacy of chloromycetin in the treatment of patients with typhoid fever and murine typhus has been commented upon elsewhere (13, 14). Neither of the cases of leptospirosis showed marked benefit from chloromycetin during the 24 to 48 hours it was given, at the end of which time the original tentative diagnosis of scrub typhus was changed, penicillin therapy was instituted, and improvement began shortly. The patient with blackwater fever recovered without clinically apparent kidney damage after institution of antimalarial and alkali therapy.

The treatment of volunteers who contracted scrub typhus in hyperendemic areas

Thirty-seven of the 75 volunteers who were exposed in hyperendemic areas of scrub typhus in the vicinity of Kuala Lumpur during the course of chemoprophylactic tests (15) developed tsutsugamushi disease. In these tests members of the control group developed scrub typhus during the second and third week after initial exposure while those individuals who received the antibiotic prophylactically, during exposure and the succeeding two weeks, remained well until the second week after drug was discontinued. The ultimate attack rate was not significantly different in the prophylactic and control groups of volunteers, and, except for the prolonged incubation period and the absence of eschar formation, there was no

appreciable difference in the disease in volunteers of the two groups.

Data on the 37 volunteers who contracted scrub typhus are given in Table IV where, in addition, information is included on Patients 44 and 45. In general, the volunteers were treated earlier in the course of their disease than were the patients discussed in the previous sections. For example, in a number of instances chloromycetin therapy was instituted on the first febrile day of illness and the average for the 37 volunteers was 3.1 days, which is exactly half that of the treated patients who acquired their disease under strictly natural conditions. Although there was some variation in the amount of drug given and the number of days over which therapy was provided, most of the patients received an initial oral dose of 4.0 gms. followed by a series of seven 0.25 gm. doses given at three hour intervals. The average duration of fever after drug therapy was started was 32.1 hours for this entire group. The averages for each of the four sub-groups consisting of those who had received chloromycetin prophylaxis and the controls in each of two field trials varied between 28.3 and 36.8 hours.

An unusual manifestation was noted in volunteers developing scrub typhus which had not previously been observed in patients who were treated symptomatically or in those mentioned in Table III who received chloromycetin therapeutically. This was the occurrence of relapses in volunteers who had apparently been cured by the initial course of drug. This phenomenon is discussed at some length in a report of the chemoprophylactic trials (15). However, it is of sufficient importance to review at this time. Twenty of the 37 volunteers who contracted tsutsugamushi disease in the two trials developed one or more relapses. The first recrudescence appeared between five to 15 days after the initial onset of disease. Since in most instances the initial therapeutic course had not exceeded 24 hours, the average interval between the last dose of drug used in the initial attack and the onset of the relapse was 7.1 days. Eight of the 20 patients had a second relapse which began on the average 6.5 days after the onset of the first recrudescence and 4.5 days after the end of therapy for the first relapse. Three of the group suffered from a third relapse. As in the first two recrudescences

cences the interval between this and the preceding febrile episode was about one week.

Patients suffering from their first relapse were treated in essentially the same manner, receiving 3.0 to 6.0 gms. of drug during a period of 24 hours or less. The average duration of the recrudescent fever after beginning therapy was 24.3 hours. Those individuals who had second relapses received 3.0 to 5.75 gms. of drug, but the method of administration differed in this group. Patient CP5 received 3.0 gms. given in a single dose. Patient CP1 received 1.0 gm. daily for five days and the others were treated for a period intermediate between the two. Irrespective of the regime these patients became afebrile within a day. The

three patients with third relapses had mild fevers in the range of 100° F. which subsided rapidly whether or not therapy was given.

The diagnosis of scrub typhus was proved by laboratory procedures in all but one of the 37 volunteers who became ill with scrub typhus. These procedures consisted of either isolation of rickettsiae from the blood or the demonstration of the development of a positive Weil-Felix reaction (see Table IV). The initial relapses were proved to be scrub typhus in the majority of cases by demonstration of rickettsemia, *i.e.*, in 11 of the 14 patients on whom attempts at isolation were made. Similarly, one of two patients examined had rickettsemia during his second relapse.

FIG. 5. CLINICAL RESPONSE OF PATIENT CP 30 TO INADEQUATE CHLOROMYCETIN THERAPY BEGUN ON THE FIFTH DAY OF DISEASE

The low grade intermittent fever subsided promptly after the second course of treatment.

* THESE VOLUNTEERS HAD RECEIVED SCRUB TYPHUS VACCINE

+ THESE EMPLOYEES WERE NEGLIGENT IN THE USE OF REPELLANT AND CONTRACTED SCRUB TYPHUS IN THE HYPERENDEMIC EXPOSURE AREA. THEIR EXPOSURE IS CONSIDERED MORE COMPARABLE TO THAT OF THE VOLUNTEERS THAN TO THAT OF THE OTHER NATIVE WORKERS EMPLOYED IN THIS AREA.

The record of volunteer Patient CP14, which is presented graphically in Figure 4, shows the usual course of the initial disease and the first relapse in the volunteers and the effect of therapy on these febrile episodes. This record also illustrates the findings in most of the individuals who had second and third relapses. It will be seen that this volunteer had a series of relatively mild febrile attacks and that he was ambulatory during most of the time covered by the chart, carrying on desk work but avoiding the more strenuous efforts of field work. The records of Patients CP4 and CP25 resemble that shown in Figure 4 in that these individuals also spent most of their time on duty between febrile episodes.

In contrast to the general rule that the volunteers who suffered from relapses were asymptomatic between their brief recurrent febrile episodes, were the findings in Patient CP30, whose record is summarized in Figure 5. This individual remained well until the 32nd day after the initial exposure which was ten days after his last prophylactic dose of chloromycetin. He was lost from observation from the 30th day after the first field exposure until the fifth day of his illness. At this time he was given 4.0 gms. of drug over a period of eight hours and became afebrile within 40 hours. As will be seen in Figure 5 the resultant

afebrile period was of relatively short duration since low grade intermittent fever occurred during the ensuing week. The temperature reached 101° F. on the 16th day after onset. At this time 3.0 gms. of drug were given in a single dose and the patient became permanently afebrile 40 hours later. It would appear that this was an instance in which the infection was controlled for only a brief period by the therapeutic regime employed. It is probable that the course of treatment used for Patient 1, who received 11.6 gms. of chloromycetin over 120 hours (Figure 2), would have been more appropriate in this instance. It may be mentioned that Patient CP30, along with CP21, spent 24 hours a day for nine days in the infected areas. These two, like the rest of the volunteers, received seven hours of supervised exposure daily but in addition they spent the remainder of the nine days of exposure in the areas serving as guards.

Incidence of eschars in patients with scrub typhus

The incidence of eschars in patients with scrub typhus has varied widely under different circumstances and in different geographic areas. Thus, during World War II the incidence of eschars observed in Allied troops from different combat areas ranged between 40 and 100 per cent (16-18). It

TABLE V
INCIDENCE OF ESCHARS IN PATIENTS WITH
SCRUB TYPHUS, KUALA LUMPUR, 1948

GROUP	RACE	NO. OF CASES	NO. WITH ESCHARS	% WITH ESCHARS
NATURALLY OCCURRING CASES	CAUCASIAN	6	3	50

	ASIATIC	70	5	7
	BOTH	84	12	14

may be noted that the absence of this sign delayed the recognition of *R. tsutsugamushi* infections in northern Australia and Malaya (10, 11).

The present observations summarized in Table V reemphasize the marked variation in incidence of eschar formation in different groups of patients. Among the 47 patients with naturally acquired scrub typhus seen in the present study, six were Caucasians and the remainder Asiatics. One-half of the Caucasians developed eschars whereas only 7 per cent of the Asiatics showed this lesion. The frequency with which eschars appeared among the 37 volunteers who acquired scrub typhus following exposure in infected areas likewise appeared to be related to race but, in addition, was dependent upon whether chemoprophylaxis had been received. Thus, none of the four Caucasians and 11 Asiatics who had received chloromycetin prophylactically during the field trial developed eschars with their attack of scrub typhus, whereas all four Caucasians and two of 18 Asiatics who did not receive chloromycetin during their exposure developed an eschar.

These findings agree with earlier observations in Malaya (10, 11) that eschars are more frequently observed in Europeans than in Asiatics. They also indicate that the prophylactic administration of the specific drug during and following exposure influenced the formation of eschars. While no factual data are available to explain the role of prophylaxis in the eschar formation, it has been postulated elsewhere (15) that during the suppression of growth of rickettsiae by the drug, sufficient local immunity developed in the cutis at the site of the infected bite to prevent subsequent development of the eschar.

Unusual cutaneous lesions in volunteers developing scrub typhus

An unusual skin eruption was observed on two of the volunteers (CP2 and CP14) in the first field trial. On the ninth day of exposure these individuals noted a number of small erythematous spots which itched slightly. These occurred in the axillae, groins, popliteal spaces, and around the waist, all areas where mite attachments are most apt to occur. These minor lesions persisted for several days and did not change during the prefebrile period when the primary eschar was developing in these two volunteers. Shortly after

the onset of fever, when the primary eschar was already well developed, vesicles having a diameter of 2 to 4 mm. and a height of 1 to 2 mm. suddenly blossomed on the erythematous lesions. These looked like early varicella pocks but fluid could not be obtained when aspiration was attempted. Each volunteer had 50 to 100 vesicles which were limited almost entirely to the trunk, occurring primarily in the axillae and groins, and around the waist. The pock-like lesions receded a day or so after chloromycetin therapy was instituted but again flared up during the first relapse of both volunteers only to subside again when the fever disappeared. One of the volunteers, who was a physician, was convinced that at least six of the vesicles developed on marked sites where mites had been observed attached.

Neither histological studies nor attempts to recover rickettsiae from the lesions were undertaken. It is not possible to say whether these lesions represented unusual allergic reactions to mite bites which became infected during the rickettsemic phase of the disease; or whether they represented aborted primary eschars, occurring at the site of bites of infected mites acquired late in the exposure period, which were controlled by chemotherapy; or whether they were unrelated to scrub typhus.

Chloromycetin in blood, spinal fluid, and milk

The blood level of chloromycetin was determined on a number of occasions in each of the treated patients listed in Table III. Similar determinations were also made on selected patients with scrub typhus from the group of volunteers. There appears to be little point in discussing the blood levels in detail. In general, the data presented in Figures 2 and 3 illustrate the types of curves obtained in the prolonged and short courses of therapy.

The levels of chloromycetin in blood and spinal fluid specimens taken simultaneously were determined in three instances. In addition, on two occasions specimens of blood and milk, obtained at the same time from one of the lactating patients, were assayed. The results summarized in Table VI indicate that the level of chloromycetin in the spinal fluid is about half that found in the blood and that similarly the levels in the milk are of this same order of magnitude.

Rickettsemia during afebrile periods

The present work brought out a fact not previously recognized, namely, that *R. tsutsugamushi* may occur in the blood at times when a patient is afebrile and essentially asymptomatic. Patient CP14, one of the volunteers in the prophylactic trial, developed a lesion in the pretibial region of his left leg on the 15th day after initial exposure

in the field. This vesicular lesion with a surrounding areola increased in size during the next few days while the patient remained ambulatory. Enlargement of the left inguinal nodes developed, and on the fifth day after its appearance the pretibial lesion was a typical eschar with a black center. It will be seen from Figure 4 that the patient had an elevation of temperature for the first time on the afternoon of the third day after the eschar was noted. A sample of blood obtained on the morning of this day contained *R. tsutsugamushi*. The rickettsial agent was again isolated from blood taken immediately before chloromycetin therapy was begun on the third febrile day of the illness. This is the first instance on record in which rickettsiae have been demonstrated in the blood prior to the febrile phase of scrub typhus.

From the very beginning of the present work we were interested in determining how rapidly rickettsiae disappeared from the blood of treated patients. Therefore, in treated Patient 1 blood samples were obtained at frequent intervals during the first two and one-half days after therapy

* THE MLD₅₀ TITER OF THIS SPECIMEN IN MICE WAS 10^{-1.5}

was begun and were used for isolation studies and for determination of chloromycetin blood levels. The data on this individual and on four other patients with scrub typhus who were investigated along these lines are given in Table VII. Several points are evident from the tabular material. In the first place, rickettsemia was demonstrated in three patients 28 to 30 hours after therapy was

begun at which time the patients were afebrile. However, the rickettsiae had disappeared from the blood of these three patients 42 to 54 hours after therapy was instituted.

It has been shown that chloromycetin, even in concentrations of 1250 $\mu\text{g.}$ per cc., has no *in vitro* rickettsiocidal activity against the agent of tsutsugamushi disease (19). Therefore, the presence

A total of 127.5 gms. of sodium p-aminobenzoate was given over a period 100 hours.

of concentrations of 50 to 100 μ g. per cc. of drug such as occurred in the patient's blood samples would not be expected to inactivate the organism. Furthermore, the relatively small amounts of drug present in the material inoculated into mice could not be expected to influence the infection in these animals.

Para-aminobenzoic acid in the treatment of scrub typhus

Para-aminobenzoic acid has been used with definitely beneficial results in the treatment of a number of rickettsial diseases (20, 21) including scrub typhus (22). Clinical results with this drug are less striking than are those obtained with the new antibiotic; nevertheless, when used relatively early in the disease, the duration of the febrile period and the mortality are reduced. Several patients with scrub typhus were treated with p-aminobenzoic acid while under our observation during the present work. The record of one of these, Patient P2, is illustrated in Figure 6. The results obtained in this individual correspond in general with those observed in the other two. The patient was admitted on the evening of the seventh day and at 8:00 p.m. received 6.0 gms. of sodium p-aminobenzoate intravenously. Between then and midnight she was given an additional 11.0 gms. of the drug by mouth. During the succeeding four days she received 25–30 gms. of sodium p-aminobenzoate daily. An adequate blood level was reached and maintained. The fever disappeared by lysis over four days and after the 12th day the patient remained afebrile. In general, the results in our hands agreed with those obtained by Tierney (22) in the treatment of 18 patients with scrub typhus in Assam.

It is our opinion that p-aminobenzoic acid has a place in the treatment of this disease when the newer therapeutic agents are not available.

Lack of toxic manifestations attributable to chloromycetin in treated patients

No significant manifestations of toxicity were attributable to the use of chloromycetin in the treatment of 84 patients mentioned in this report; this includes not only 69 patients with scrub typhus but the additional group of 15 with other diseases. The occurrence of mild cerebral stimulation in persons receiving single 4.0 gm. doses of drug has

been mentioned elsewhere as has the fact that the administration of 12.0 to 20.0 gms. of drug over a period of three weeks to 34 volunteers in the chemoprophylactic studies was without untoward effect (15). Most of the treated patients who had acquired their scrub typhus under strictly natural conditions received considerably smaller amounts of drug than did those volunteers in the chemoprophylactic tests who suffered from relapses. Even in the latter group no evidence of toxicity was demonstrated. It may be mentioned that certain of these volunteers, during the course of their prophylaxis and throughout their treatment, received 38.0 to 46.3 gms. of drug over a period of about eight weeks (see Table VIII). The administration of such large amounts of drug over an appreciable period of time indicates that patients are not readily sensitized to this substance. Even those individuals who received the compound intermittently remained free of evidence of sensitivity.

Red blood cell counts (or hemoglobin levels) and leukocyte counts were done, in so far as possible, both before treatment and during convalescence on all patients suffering from scrub typhus who received chloromycetin therapeutically. In five instances, when severely ill patients were treated in estate hospitals, it was not practicable to obtain pretreatment values. In the evaluation of data obtained in this fashion, it may be pointed out that a significant drop in red blood cell count, *i.e.*, 0.9 million cells or 2.5 gms. of hemoglobin, occurs during the first two weeks of the untreated disease (23).

Of the 64 patients who received chloromycetin therapy for scrub typhus and who were adequately studied, 27 showed a drop in red blood cell count. The maximum decrease observed for any one patient was 1.10 million, and the average decrease for the entire group of 64 was 0.11 million. These reductions in red blood cell count are of the same order as those occurring in untreated patients (23). In the present group, there was an average rise of leukocyte count from 6,700 to 7,400; this also occurred frequently in untreated cases during convalescence. It is interesting to note that chloromycetin was administered to one patient whose leukocyte count at the beginning of therapy was only 1,700. His recovery was uneventful, and, at the time of discharge, the white

count had risen to 4,200. Routine urine analyses, performed during the acute illness and convalescence, demonstrated no abnormalities that were not present before therapy was initiated. In summary, no significant change of the blood or urine attributable to the administration of chloromycetin was noted.

DISCUSSION

The observations reported at this time clearly indicate that chloromycetin is a highly effective therapeutic agent in the treatment of scrub typhus in man. When properly used, it may be expected to produce obvious improvement in the patient's condition in a matter of a few hours and to render him afebrile in about 30 hours.

The short course of therapy which was used extensively in the present studies consisted of an initial oral administration of approximately 60 mg./kg. of body weight which was followed by an additional 1.5 to 2.0 gms. of drug given as 0.25 gm. tablets at three-hour intervals. This regime appeared to be satisfactory in those patients who acquired their disease during exposure while pursuing their normal occupational duties. On the average these patients were first treated 6.2 days after onset of illness. These individuals all became afebrile in an average of 31.8 hours and remained afebrile thereafter.

The results in volunteers who were purposely exposed in hyperendemic areas of scrub typhus during the course of chemoprophylactic field trials differed from that observed in the patients who acquired the disease during normal occupational exposure in infected areas. Fifty-four per cent of the volunteers who developed scrub typhus subsequently had one or more relapses following the apparent cure which had resulted from the initial treatment. Although the volunteers who had relapses became permanently afebrile, on the average, on the 17th day after onset of original illness, nevertheless, a number of them did not return to full strength and vigor until two or three weeks later. Various factors which might have accounted for the relapse rate in the volunteers have been discussed at length in another paper (15). Among these factors only two that need be mentioned here are (a) the infecting dose was undoubtedly heavy and was probably repeated over a period of days in the volunteers, and (b) treat-

ment was begun appreciably earlier in these persons than in those who acquired their infection naturally. The hypothesis which is presently preferred to account for these relapses is as follows: "The rickettsiostatic effect of chloromycetin was dissipated within a short time after therapy was stopped. At this early stage of infection the immune mechanism of the host had not yet had time to respond adequately to the rickettsial agent. Therefore, after a temporary interruption due to drug, the growth of the rickettsiae proceeded at an unabated rate. Finally, after an interval of five to 10 days, the rickettsial multiplication reached a level sufficient to elicit clinical manifestations again" (15).

The variation in incidence of eschars in patients of different races has been previously observed with scrub typhus (10, 11b) and was the experience in the present studies on persons who acquired the disease during normal occupational duties. Furthermore, the high incidence of eschars in the Caucasians in the control chemoprophylactic group and the relatively low incidence in the Asiatics in this group was to be expected. However, the absence of eschars was an unexpected observation in those persons who developed scrub typhus after chemoprophylaxis was discontinued. It has been suggested that local cutaneous immunity developed in these persons during the subclinical infection which was brewing during the course of prophylaxis.

SUMMARY AND CONCLUSIONS

Sixty-nine patients with scrub typhus were treated with chloromycetin. Although some of these were desperately ill when therapy was instituted, there were no deaths in this group. The mortality rate among the 19 untreated patients observed during the present work was slightly greater than 5 per cent; this agrees well with the figure of 6.7 per cent in a series of 164 patients observed by Lewthwaite in Malaya (11a).

The most commonly used therapeutic regime in the present work employed about 6.0 gms. of chloromycetin orally over a period of 24 hours. This was adequate to render patients, who acquired their disease naturally, afebrile within an average of 32 hours irrespective of the time during the course of the disease when the drug was started. These patients convalesced rapidly and had no

relapses. In contrast 54 per cent of the 37 volunteers who acquired scrub typhus developed relapses; these persons had been exposed for a number of days in hyperendemic areas during chemoprophylactic field trials. It is apparent that the course of therapy given early in the disease to volunteers was not adequate to control permanently the infection in them. However, the recrudescence of disease was controlled without difficulty when chloromycetin was again administered. Additional information is needed before final conclusions can be drawn about the optimal therapeutic regime. In the meantime, it is recommended that all patients with scrub typhus, irrespective of the time when treatment is started, be given an initial oral dose of 60 mg./kg. of body weight and that this to be followed by 0.25 gm. doses of drug at three-hour intervals for at least 24 hours. If a recrudescence of fever occurs, the course should be repeated.

Chloromycetin is of low toxicity for man. No significant untoward effects were observed in any of the 84 patients who received the drug in the current studies.

Chloromycetin appears in the spinal fluid and milk of human beings reaching levels about half that in the blood.

Rickettsemia may occur for short periods before fever begins in tsutsugamushi disease and for a number of hours after treated patients become afebrile.

ACKNOWLEDGMENTS

The authors wish to thank the following members of the Royal Army Medical Corps, Lt. Col. R. H. Robinson, Officer in Charge, Major C. J. Williams, Medical Specialist, Lt. H. M. Giles, Graded Medical Specialist, and Major A. J. Rump, Registrar, of the Military Hospital, Kuala Lumpur, for their cooperation in the clinical evaluation of chloromycetin therapy of scrub typhus in military patients. Similarly, Dr. F. L. Choon, General Medical Officer, and Dr. C. N. Seong, Medical Officer, were of great help in the civilian General Hospital. Grateful acknowledgment is also made of the assistance provided by Miss E. B. Cheek, Dr. S. R. Savoor and other members of the staff of the Institute for Medical Research.

CHANGES IN LIVER GLYCOGEN STUDIED BY THE NEEDLE ASPIRATION TECHNIC IN PATIENTS WITH DIABETIC KETOSIS. WITH A METHOD FOR THE ESTIMATION OF GLYCOGEN FROM HISTOLOGIC PREPARATIONS¹

By PHILIP K. BONDY, WALTER H. SHELDON, AND LILLIAN D. EVANS

(From the Departments of Medicine and Pathology, Emory University School of Medicine, and Grady Memorial Hospital, Atlanta, Ga.)

(Received for publication March 16, 1949)

Previous attempts to estimate the glycogen content of the human liver were based on determinations performed on material obtained by operative biopsy or from postmortem specimens. Observations on animals have shown that these procedures may introduce an important error through the effect of the commonly used anesthetic agents, or of trauma, before the specimen is obtained. The development of a technic for the removal of small specimens of liver by aspiration biopsy is well adapted to the study of glycogen metabolism, for it avoids the uncertain effects of premedication, general anesthesia and the trauma of operation. By this method serial biopsies of the liver have been obtained in a study of patients under treatment for diabetic acidosis.

METHODS

Liver tissue was obtained by needle biopsy, using the Vim-Silverman needle, under local procaine infiltration. With practice, it was possible to obtain an adequate specimen in less than three seconds from the time of insertion of the needle into the substance of the liver. Speed was desirable, since patients in severe acidosis were unable to hold their breath. The specimens were immediately fixed in iced absolute alcohol or Rossman's fixative.

Plasma carbon dioxide combining powers were determined by the method of Van Slyke and Neill (1). The Folin-Wu method was used for the determination of blood glucose (2).

THE TECHNIC FOR THE ESTIMATION OF HEPATIC GLYCOGEN

At first, the glycogen concentration was determined by the chemical method of Good, Kramer and Somogyi (3). This technic was unsatisfactory, however, since without histologic examination it was impossible to be

certain that the entire specimen submitted to analysis consisted of hepatic parenchyma. On several occasions, specimens obtained by needle biopsy have included bits of skeletal muscle, fat or fibrous tissue with the liver specimen. Had the entire contents of the needle been analyzed, the results would not have been representative of liver glycogen. It therefore seemed essential to examine microscopically the material which was to be analyzed. To do this, some histochemical method of estimating glycogen had to be adopted.

It had previously been shown by Deane, Nesbitt and Hastings (4) that the staining intensity of glycogen in rat livers was proportional to the concentration of glycogen determined by the usual chemical methods. This fact was used to develop a method of estimating the glycogen content of the specimens obtained by biopsy.

The tissue was prepared and stained for glycogen by the method of Gomori (5) under carefully controlled uniform conditions. No counterstain was used. Control slides prepared from tissue digested by salivary amylase demonstrated that only glycogen-containing material was stained by this method.

The optical density of the stained glycogen was determined photometrically. A photomicrographic apparatus was set up in a dark room. The slide to be examined was placed upon the mechanical stage and its image projected, at a magnification of approximately 500 \times upon a ground glass screen with a central clear zone. Over the clear window was fixed the aperture of the photoelectric cell of a Photovolt electronic photometer. With the substage lamp turned off, the photometer was adjusted to read "0.0." The lamp was then turned on, and the slide scanned in an area without tissue. The substage diaphragm was then adjusted so that the photometer reading was "100.0." This step automatically corrects for variations of color or thickness of the slide, coverslip or mounting medium. The image of the preparation was then moved across the screen so that successive random readings of the light transmitted through the tissue could be made. Because of the manner of adjustment, the galvanometer readings represented "percent transmission." These readings were translated to optical density by the application of the formula: $d = 2 - \log T$. Unstained tissue had no detectable optical density. Since glycogen stains black by the method used, it was possible to make readings using a white source of light without filters. A method similar to this has

¹ Presented in part at the Southern Section, American Federation for Clinical Research, New Orleans, La., January 29, 1948, and at the American Physiological Society, Atlantic City, N. J., March 18, 1948.

FIG. 1. RELATIONSHIP OF OPTICAL DENSITY OF HISTOCHEMICAL PREPARATION TO GLYCOGEN CONTENT OF RAT LIVERS

been described by Buchanan and Hill for the estimation of myelin (6).

It has been observed by Gomori and Goldner (7) that there may be considerable focal variation of the glycogen content of liver cells. Hédon and Loubatières, however, analyzing fairly large aliquots of liver, have shown (8) the maximal variation within the liver to be less than 10 per cent. It was necessary, therefore, to determine the mean of a series of readings for each specimen in order to obtain an adequate sampling of the glycogen content of the specimen. The minimum number of observations which would afford the desired accuracy was ascertained by making 100 random readings of a single specimen. With 100 readings, the mean was 0.39 with a standard error of ± 0.012 optical density units. With 20 readings, the standard error ranged from .014 to .022. Ten readings produced standard errors ranging from 0.026 to 0.043. It was felt that the standard error of less than 10 per cent provided by 20 readings was sufficiently accurate for the purposes of the present investigation.

In order to estimate the accuracy of the method, a series of determinations were made comparing the chemical methods of assaying glycogen with the results of the histochemical estimation on the same specimen. A group of rats was injected with glucose whereas others were fasted for various periods to provide liver tissue with varying glycogen contents. The animals were then sacrificed. Immediately after death, adjacent specimens of liver were obtained for the determination of glycogen by the method of Good, Kramer and Somogyi (3) and for histochemical preparations. The regression of optical

density on the chemical glycogen value was calculated. The significance of the regression was determined by dividing the slope by its standard error, giving a value of p^2 of less than 0.01 (Figure 1). The standard deviation of the points about the regression line was ± 0.149 . It is of some importance that the standard deviation of the 100 readings performed on a single preparation was ± 0.121 . In two separate sets of data, the degree of variance caused by the method of observation appears to be almost the same, indicating that the technic is uniform and the results reproducible.

A further conclusion may be drawn from the close agreement of the standard deviations of the regression curve and of a single preparation examined many times. Since the variance of the points about the regression curve is no greater than the variance of a series of optical densities determined for a single specimen, it appears that the entire scatter of points on the regression curve can be accounted for by the limitations of the method of determining optical density. It is therefore unnecessary to suppose that part of the scatter may be caused by unequal distribution of glycogen through the liver. Apparently the mean of 20 readings of the histologic section offers a sample adequate for controlling local variations of glycogen. The limiting factor of accuracy therefore appears to arise, not from the unequal distribution of liver glycogen, but from the limitations of the scanning technic.

²" p " estimated from Fisher's table of p (23). A significant value is considered to be one less than 0.02. Slope = $.0827 \pm .0031$.

* The upper figure refers to total dosage; the lower figure is the amount given intravenously in the clyses. Unless otherwise specified all insulin was regular insulin.

† Administered as a routine injection of protamine zinc insulin five hours before the biopsy.

The standard error of the glycogen determination is approximately ± 0.022 . The limitation of the ability of the method to distinguish differences of glycogen concentration is, therefore, $\pm 0.044 d$ in the regression equation, $d = 0.108 + 0.0827 G$, or a difference of glycogen concentration of 0.5 gm./100 gm. of liver. The sensitivity of this technic is therefore limited, since it cannot detect small alterations of concentration. This disadvantage seems to be outweighed by the opportunity to examine under the microscope the tissue which is to be analyzed, and by the assurance that it is the glycogen concentration of the liver cells which is actually being determined.

New sets of histologic preparations were made from the same blocks of rat liver for repeated histochemical assays. It was found that the slope of the regression curve varied somewhat in the different sets. In spite of this, the relationship of the various samples to one another remained constant. The variation of the slope therefore appeared not to be due to errors of the method of determining optical density, but to variations in the intensity of staining reaction in successive runs of slides. To control this, it was necessary to set up a new reference curve for the calibration of each batch of histologic preparations. This was done by running sections from four of the rat liver preparations previously described along with the biopsy specimens, taking care to treat both standards and unknowns in a uniform manner with regard to sectioning, staining and mounting. The optical densities of the standards were plotted, an estimated regression line drawn, and the glycogen content of the unknown specimens read from this line. All of the biopsies from a given subject were analyzed in the same batch.

CLINICAL MATERIAL

Six patients admitted to the medical service of Grady Memorial Hospital with diabetic acidosis of varying degrees of severity were subjected to needle biopsy of the liver before the institution of treatment. In five cases a second biopsy was obtained after varying periods of therapy. No ill effects attributable to biopsy were observed. The treatment used consisted of the administration of insulin, glucose and salt solutions. The details are given in Table I.

Liver biopsies by the same technic were also done on three patients hospitalized for various acute illnesses not involving the liver or carbohydrate metabolism. The first biopsy was done under basal conditions and was followed by another biopsy in two of these patients after they had been given a standard breakfast which supplied more than 50 gm. of carbohydrate. At the time of these examinations, all patients were convalescent and had been afebrile for more than 48 hours. All had been eating a diet containing more than 300 gm. of carbohydrate for three or more days before the test.

RESULTS

The values obtained in the normal basal individuals were 2.8, 3.2 and 4.7 gm./100 gm. These values are somewhat higher than the mean value of 2.0 per cent found by Young, Abels and Homburger (9) who obtained their specimens during laparotomy, and by Hildes, Sherlock and Walshe

(10) who employed the aspiration biopsy technic and used a chemical technic for analysis of glycogen content. The present figures, however, fall within the range of normal observations obtained in both of the other normal series. Two subjects were examined one hour after breakfast. In these instances there was an increase of glycogen content of 1.5 and 2.3 gm./100 gm. No comparable observations are available in intact human beings, since the results of Young, Abels and Homburger after the administration of glucose were obtained from patients other than those furnishing specimens prior to carbohydrate administration.

The glycogen content of the livers of patients with untreated diabetic ketosis ranged from 0.3 to 7.0 gm./100 gm. (Table I). If patient Gr. H. is omitted from the calculation, there is a correlation between the carbon dioxide combining power and the liver glycogen concentration. The justification for the elimination of patient Gr. H. from this series is discussed below.

In each patient there was an elevation of the liver glycogen after treatment. If the rate of increase of glycogen in gm./100 gm./hr. is calculated for each patient, and compared with the duration of treatment before the second biopsy, a steady increase in the rate of glycogen deposition is found from a minimum of 0.3 gm./100 gm./hr. after one hour of treatment, to a maximum of 0.72 gm./100 gm./hr. after six hours of therapy.

DISCUSSION

The finding of normal values for the glycogen content of the liver under basal conditions presents additional evidence of the validity of the method used for estimating glycogen in the present study. The fact that the values range somewhat higher than the mean values of other series may be fortuitous in view of the small number of observations. It should be noted, however, that in the series presented by Young *et al.* (9) the patients received "routine preoperative preparation," which may have included morphine. Most of their specimens were obtained during laparotomy under ether anesthesia. The absence of pharmacologic and psychic stimulation prior to biopsy in the present series may account for the somewhat higher glycogen values in our patients.

The livers of untreated diabetic patients contained less glycogen than normal, except in two

cases. One patient, M. S., was mildly decompensated. Her carbon dioxide combining power was almost normal (48.7 vol. per cent), and she recovered spontaneously under the influence of the protamine zinc insulin which she had taken five hours previously. The other patient, Gr. H., may represent a special case, and is discussed below. If this patient is omitted from consideration, there is a correlation between the carbon dioxide combining power and the liver glycogen concentration ($r = 0.939$; p less than 0.02). It therefore appears that the degree of glycogen depletion may have been related to the severity of the acidosis in five of the six patients.

It has generally been stated that the liver glycogen tends to be depressed in diabetic acidosis (11). It has been shown, however, that the liver glycogen of the pancreatectomized dog (12) or alloxanized rat (13, 14) or rabbit (14) may be normal at times when the animal shows signs of severe diabetes. Glycosuria, hyperglycemia and ketonuria may be found in the presence of normal or elevated liver glycogen concentrations. In fact, alloxan-diabetic rats tend to maintain their liver glycogen reserves better during fasting than the normal rat (15). Only when the animal enters a stage of terminal acidosis does the glycogen level fall (16).

Previous studies of liver glycogen concentration in human diabetics have been confusing because the tissue was examined only after death (17, 18) or because, in many cases, the specimens were obtained after treatment with insulin (19, 20). Hildes *et al.* (10), using a technic similar to that used in the present study, determined the glycogen content of the liver of several diabetic patients. Their subjects, although ketonuric, were not severely decompensated, since there was only one in the group with a carbon dioxide combining power of less than 49 vol. per cent. In their series, the liver glycogen concentrations were normal.

The present series represents the first group of human diabetics in severe acidosis whose liver glycogens have been estimated prior to treatment. The relationship between the severity of acidosis and the depression of liver glycogen appears to agree with the results obtained in animals. It is of interest, however, that one patient (Gr. H.) had an elevated liver glycogen concentration while in severe acidosis. Thus, in humans as in ani-

mals, it is possible to have advanced diabetic ketosis in the presence of an elevated liver glycogen concentration.

There is probably, therefore, no causal relationship between depression of liver glycogen and the development of acidosis in diabetes. On the contrary, the nausea and vomiting of ketosis may so restrict the food intake as to play a significant role in the development of liver glycogen depletion. We have no evidence upon which to decide which factor is primary.

After the institution of treatment, there was an increase in the hepatic glycogen concentration in all patients examined. This effect of therapy had previously been noted, in a qualitative observation (21). Following the institution of therapy, the rate of glycogen accumulation by the liver increased over a seven-hour observation period. This finding agrees with the studies of splanchnic glucose balance in human beings during treatment for diabetic ketosis (22). In these patients, there was a latent period of approximately one hour after the administration of large amounts of insulin intravenously before the splanchnic system began to retain glucose. It appears probable that even after the administration of large doses of insulin and glucose, some time must elapse before the liver achieves its maximal rate of glycogen deposition.

One patient, Gr. H., had a liver glycogen concentration far higher than any of the others, and higher than any of the normal subjects in this or other series (9, 10). There can be no doubt that the patient was suffering from severe diabetic acidosis (see appended case history). In certain respects, however, she was different from the other patients in the series. She was very obese, while the other patients were thin or normal in nutrition. The history of polyuria and polydipsia extended back for a period of two years; but she had felt well until, following a trauma, she suddenly developed ketosis. Her acidosis was moderately insulin-resistant, requiring more than 800 units in 24 hours; but when placed on a stringent reducing diet, she lost 20 lbs. and was controlled well without insulin. The other patients in this series had taken insulin for prolonged periods, and could not be controlled by diet alone. It therefore seems that patient Gr. H. falls into the group of mild diabetics with obesity. The other patients appear to have suffered from a more severe and,

possibly, a basically different type of disease. It may be that this difference explains the fact that, of all the patients examined, only patient Gr. H. had an elevated liver glycogen concentration during severe ketosis.

SUMMARY

The liver glycogen content of diabetic and non-diabetic patients has been estimated by a method of determining the optical density of histologic preparations. The tissue was obtained by needle aspiration and was prepared by Gomori's histochemical technic. The method was sensitive to changes in glycogen concentration of 0.5 gm./100 gm. and appeared to furnish an adequate estimate of the glycogen of the entire liver.

Glycogen determinations were made on the livers of three non-diabetic fasting patients, and in two of them after breakfast. The fasting values ranged from 2.8 to 4.7 per cent. A significant increase in the liver glycogen was observed after a meal.

Six decompensated diabetic patients were subjected to biopsy. In all cases except one, there was a decrease of liver glycogen proportional to the severity of the ketosis. After treatment, all patients showed an increase of liver glycogen.

One patient had a liver glycogen concentration of 7.0 per cent during severe ketosis. Because of her obesity and low insulin requirement, it is suggested that she may have had a type of diabetes different from the other subjects. In spite of her high initial glycogen level, this patient also deposited glycogen in her liver during therapy.

APPENDIX

Gr. H., 27 year old negress, was admitted to the medical service of Grady Memorial Hospital on February 14, 1948, because of abdominal pain. She had noticed frequency of urination, beginning in 1945, and had moderate increase in thirst from that time. One week before admission she had been kicked in the abdomen. Following this, she developed abdominal pain, increased thirst and urination. Three days prior to admission she began to vomit. Eight hours before admission she developed shortness of breath.

One sister suffered from diabetes mellitus. The patient had adequately treated persistently seropositive syphilis. Two stillbirths had occurred, the most recent being three months before admission.

The temperature was 99.6, pulse 110, respirations 36, blood pressure 120/80, and weight 247 lbs. The physical

examination showed an uncomfortable, mildly disoriented obese negroess who lay panting in bed. She was severely dehydrated. There were intertrigo, vaginitis and evidence of chronic pelvic inflammatory disease. The examination was otherwise not remarkable.

The Kahn test was positive (4 Kalin Units), the urine positive for sugar (four plus) and acetone (three plus). The red blood count was 5,850,000, the hematocrit 49 per cent and the sedimentation rate (Westergren) 48 mm./hr. The white count was 11,550, with 74 per cent polymorphonuclear forms. The admission blood glucose level was 420 mg./100 ml., and the carbon dioxide combining power 13.9 vol. per cent (6.3 mM/L).

The acidosis was controlled, in a period of 24 hours, after the administration of a total of 810 units of regular insulin, 6500 ml. of normal saline and 550 gm. of glucose parenterally. After a period of observation in the hospital, she was discharged on an 820 calorie reducing diet, with 60 units of protamine zinc insulin daily. Over a period of three months, her insulin requirement gradually dropped so that, by May 1948, she was aglycosuric without insulin. During this time she lost 20 lbs. of weight.

STUDIES OF THE DISTRIBUTION OF RADIOACTIVE IODINE IN THE PRESENCE OF SERUM AND URINE IN DIFFERENT LEVELS OF THYROID FUNCTION

There is probably a relationship between the development of thyroid function and the distribution of radioactive iodine in the presence of serum and urine in different levels of thyroid function. ROBERT H. WILLIAMS, HERBERT JAFFE, AND BEATRICE BERNSTEIN (From the Thorndike Memorial Laboratory, Second and Fourth Medical Services [Harvard], Boston City Hospital, the Department of Medicine, Harvard Medical School, Boston, Massachusetts, and the Department of Medicine, University of Washington, Seattle, Washington)

(Received for publication March 19, 1948)

One of the earliest uses of radioiodine was as a tool for the study of thyroid physiology (1-7). Estimations of the relative quantities of isotope stored in the thyroid have been made by means of a Geiger-Müller tube held over the gland and by determining the amount present in the urine and blood. The rate with which the level of radioiodine changes in these compartments has also been studied (7, 8).

In subjects with euthyroidism, radioiodine was found (8) to be excreted rapidly, within a few hours after its administration, but a plateau tended to appear after 48 hours. In myxedematous individuals, excretion was slower initially but it was more persistent, requiring four days or more; the total amount excreted after several days was greater in myxedematous subjects than in normal or thyrotoxic ones. In untreated thyrotoxic patients the rate of excretion was less than in either of the other two groups. The curves describing excretion became asymptotic relatively quickly.

The differences in the metabolism of iodine in various functional states of the thyroid have prompted an investigation of the usefulness of radioiodine as a diagnostic test. One of the best tests not dealing with radioiodine that has been available is the determination of the protein-bound iodine of the plasma (9). This test is so long and difficult that it can be performed satisfactorily only under the direction of a few highly qualified individuals and even then some overlapping in the values for different degrees of thyroid function may be found (10). Moreover, the test is unreliable if the patient has recently received iodine in organic form and if highly scrupulous technique is not followed in the collection of the plasma as well as in the determination. It seemed to us that in some institutions it might be possible to use radioiodine in tests which would be more accurate,

simpler and more rapid. It appears logical to assume that the quantity of protein-bound radioiodine in the serum, after the administration of tracer doses, might indicate the relative rate of manufacture of the thyroid hormone and its release into the blood stream. Of course, the values obtained would represent only an approximate balance between these two factors and the quantity of the hormone stored in the various fluids and tissues of the body, including the thyroid; also between the amount metabolized and excreted. Nevertheless, with methods not using the radioiodine, not only do these difficulties in interpretation exist, but also it is not possible to determine the time required for the changes to occur. The latter aspect would seem to be a very important one.

METHODS

Two types of study were conducted following the administration of a tracer dose of radioiodine subcutaneously. In one, frequent specimens of blood and urine were collected during a 24-hour interval, for a determination of the proportion of isotope present. In the other study, which consisted of a larger number of patients, urine was saved for 24 hours and a single specimen of blood was taken at the end of this interval. I^{131} obtained from Clinton Laboratories, Oak Ridge, Tennessee, was used for the studies; no carrier was added.

Determination of the radioiodine in the specimens was by the methods previously described (11). Trichloroacetic acid was used for precipitation of protein-bound isotope. The "DI" (diiodotyrosine iodide) fraction was separated from the "TI" (thyroxine iodide) by butyl alcohol precipitation (9).

In the first experiment there were seven individuals with euthyroidism, four with thyrotoxicosis, three with athyreosis and one with Addison's disease. The patients with thyrotoxicosis had had no treatment. Those with athyreosis were in a state of euthyroidism as a result of therapy with desiccated thyroid, thereby affording an opportunity to observe the effects of the thyroid upon

for more than one week preceding the radioiodine. Each of the seven patients had a goiter. Very few of the subjects in this experiment were hospitalized.

The first experiment are shown subjects with euthyroidism and creososis excreted radioiodine in the rapidly than did the patients creososis. None of the latter group excreted 20 per cent of the injected radioiodine at 24 hours, whereas each of the euthyroid subjects excreted distinctly more. The myxedematous subjects excreted the same quantity of isotope at the end of four hours. In the creososis disease, the excretion of radioiodine and its concentration in the

Each patient was given 100 microcuries of radioiodine (I^{131}) subcutaneously without any carrier. PBI* indicates the protein-bound radioiodine. All values are expressed with reference to the dose of isotope administered.

serum were within normal range. During the first four hours the concentration of total radioiodine in the serum of thyrotoxic patients tended to be lower than in the subjects with euthyroidism or

athyreosis. It can be observed in Figure 1 that two of the thyrotoxic patients had a second rise in the concentration of isotope. The quantity of protein-bound radioiodine rapidly reached a pla-

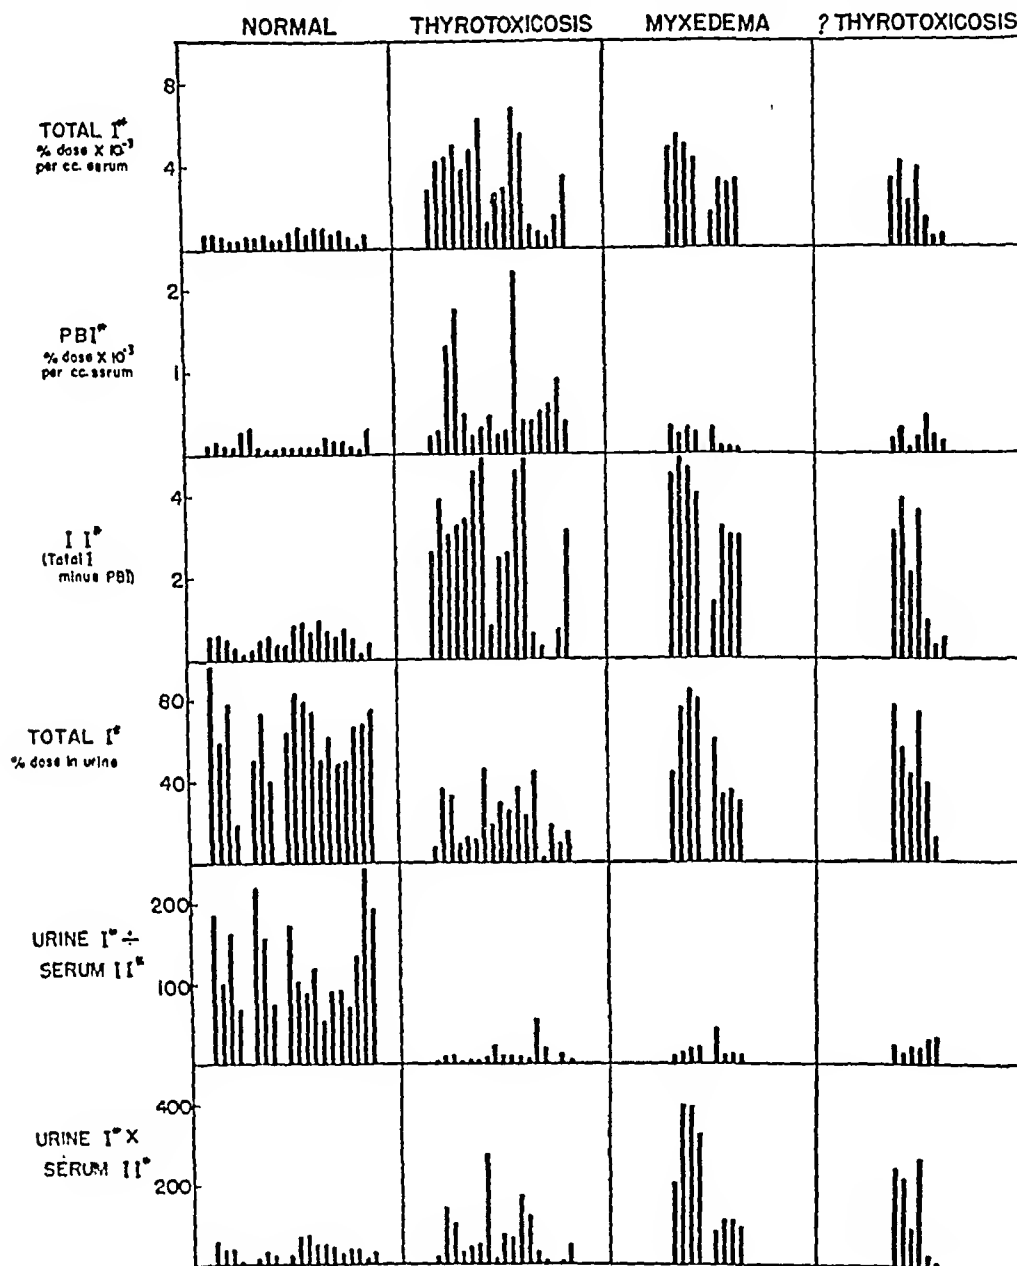

FIG. 2

The serum specimens were obtained 24 hours following the administration of radioiodine; during this interval all urine was saved for analysis; two patients neglected to collect urine. The quantity of radioiodine in inorganic (II*) form in the serum was derived by subtracting the protein-bound radioiodine (PBI*) from the total radioiodine content of serum. The reasons for empirically dividing and multiplying the values for the radioiodine in urine by the inorganic radioiodine in the serum are discussed in the text. The data shown in the seventh column of the group with "? thyrotoxicosis" are those of a patient who was subsequently shown not to have thyrotoxicity. Unfortunately, this patient failed to save all of his urine. The diagnosis of the individual with data presented in the sixth column is still questionable. In four patients myxedema was primary and in the other four (last four columns) it was secondary.

FIG. 3

These data were collected upon some of the patients represented in Figure 2.

teau in the individuals with euthyroidism and athyreosis. In the ones with thyrotoxicosis the increase was slow in the first few hours, but after 24 hours it was markedly higher in three of the four thyrotoxics than in any other subject. These observations prompted the performance of the second experiment, the results of which are shown in Figure 2.

The concentration in the serum of total radioiodine was distinctly greater in the patients with thyrotoxicosis than it was in normal individuals. In considering these findings in conjunction with the subnormal excretion of radioiodine in the urine within a 24-hour interval, it must be borne in

mind, as illustrated in Figure 1, that during several hours the concentration of total radioiodine in the serum was less in the thyrotoxic subjects than in normals. Moreover, in the former group, during the latter part of the 24-hour interval more of the radioiodine was protein-bound and thus less available for excretion.

The concentration of total and inorganic radioiodine serum of myxedematous patients was greater than normal, while the protein-bound radioiodine of the serum and the quantity of isotope in the urine were essentially normal. As to why there should be the discrepancies in the ratios of inorganic iodine in the serum and the quantity in

the urine, the answer is not clear. However, we attempted to emphasize these discrepancies in the different groups by empirically dividing the urine values by the serum inorganic iodine, and, also by multiplying them. As seen in Figure 2, there is a marked difference in the ratio of urine to serum values in the normal group as compared to the others. The product of the values is distinctly greater than normal in each of the subjects with athyreosis; it is also greater in some, but not all, of the thyrotoxic patients.

In serum of some of the patients the diiodotyrosine radioiodine and thyroxine radioiodine fractions were determined (Figure 3). No very striking difference in these fractions was observed in the various groups. The ratio of thyroxine to diiodotyrosine tended to be somewhat greater in the thyrotoxic patients, but there is too much overlapping of values to be of practical significance. On the other hand, the ratio of diiodotyrosine radioiodine to total radioiodine is definitely greater in the normal subjects than in the others. The tendency in normals for a greater ratio of thyroxine radioiodine to total radioiodine was an unexpected finding.

DISCUSSION

All of the indirect methods that have been proposed for the evaluation of the functional state of the thyroid gland by the determination of its uptake of radioiodine are associated with certain inaccuracies. Among these are the variations in thickness and contour of the neck, innumerable factors affecting kidney function, differences in the volume of the fluid compartments, and probably the rate of metabolism of the thyroid hormone and of its synthesis and concentration in non-thyroid tissues. Although Hertz, Hamilton and Soley and their colleagues (1-5), respectively, found that patients with hyperthyroidism accumulated a larger proportion of the tracer dose in the thyroid than did normal subjects, Astwood and Stanley (12) found that the concentration gradients of the group with thyrotoxicosis was not significantly above the normal range. The failure of the latter investigators to administer any carrier iodine might account for some of the difference in results. Whereas some investigators (3, 4) have measured the excretion of radioiodine in the urine as an index to the quantity retained in the thyroid gland, a

poor correlation has been found (13) between determinations of this type and direct measurements over the thyroid. However, all of the other clinical tests of thyroid function are beset with difficulties.

On the basis of data which we have presented, as well as those of others, determinations of the proportion of a tracer dose excreted in the urine are of diagnostic importance, but are not infallible. The measurements of the total radioiodine concentration in the serum, or of the measurements of the protein-bound thyroxine and diiodotyrosine radioiodine components did not demonstrate as clear a differentiation of the various levels of thyroid function as was desired. Nevertheless, it is believed that these estimations and certain ones of the ratios, that have been discussed, may be of some significance. It seems likely that greater differentiations in the protein-bound radioiodine components could be demonstrated if longer intervals were permitted to elapse before collecting the specimens, or by following the rate of the changes.

SUMMARY

Studies were conducted using radioiodine for the evaluation of different degrees of thyroid function, as found in subjects with thyrotoxicosis, athyreosis, or euthyroidism. Following the administration of 100 microcuries of radioiodine (I^{131}) carrier free, it was confirmed that thyrotoxic patients excreted less of the isotope in the urine than did the other groups. Although the concentration in the serum of total radioiodine tended to be less in the thyrotoxic group than in the others, within the first few hours, after 24 hours the total radioiodine and its protein-bound, thyroxine, and inorganic radioiodine components tended to be supernormal. In the group with athyreosis the total and inorganic radioiodine concentrations were supernormal. The ratio of diiodotyrosine radioiodine to thyroxine radioiodine, as well as a somewhat empirically calculated ratio of urine radioiodine and serum inorganic radioiodine, was distinctly less in the patients with thyrotoxicosis or athyreosis than in the normals. The product of the radioiodine of the urine and of the inorganic form of the serum was distinctly greater in the subjects with athyreosis than in normals and tended to be

greater in the former group than in the ones with thyrotoxicosis.

There was no good correlation of the results with the various degrees of thyrotoxicity.

Tests of the type reported, like all of the others of thyroid function, should be considered in conjunction with the clinical findings.

EFFECTS OF ADRENOCORTICOTROPHIC HORMONE ON NEUROMUSCULAR FUNCTION IN PATIENTS WITH MYASTHENIA GRAVIS¹

BY CLARA TORDA AND HAROLD G. WOLFF

(From the New York Hospital, the Kingsbridge Hospital [V. A.], and the Departments of Medicine [Neurology] and Psychiatry, Cornell University Medical College, New York, N. Y.)

(Received for publication June 2, 1949)

The adrenocorticotrophic hormone of the pituitary gland has been administered to patients with myasthenia gravis mainly on the basis of the following observations and inferences: (1) the immediate cause of the symptoms of myasthenia gravis is a decrease of acetylcholine synthesis (1-4); (2) administration of the adrenocorticotrophic hormone increases acetylcholine synthesis *in vivo* (5); (3) increase of the lymphatic tissue (round-cell infiltration of various organs, mainly striated muscle [6]) and "hyperfunctioning" thymus (7) have been found in patients with myasthenia gravis. Tissue fractionation studies (8, 9) have shown that one of the sources of the substances that inhibit acetylcholine synthesis is the thymus. Administration of the adrenocorticotrophic hormone induces reduction in the mass of the thymus and the lymphatic tissue (10, 11); (4) removal of the pituitary gland in rats induces changes in the electromyogram (12) that closely resemble the abnormalities noted in patients with myasthenia gravis (13, 14); (5) the pituitary gland of several patients who died of myasthenia gravis showed accumulation of an eosinophilic colloid material suggesting altered function of the gland (15-19).

This report aims to illuminate the nature of myasthenia gravis by a further analysis of its phenomenology. Therapeutic implications are outside its scope.

MATERIAL

The effect of the administration of adrenocorticotrophic hormone of the pituitary gland was studied in five patients moderately to severely ill with myasthenia gravis.²

¹Published with permission of the Chief Medical Director, Department of Medicine and Surgery, Veterans Administration, who assumes no responsibility for the opinions expressed or conclusions drawn by the authors.

²Since the completion of this manuscript three additional patients with myasthenia gravis have been given

Patient R. G., a 45 year old woman, had had myasthenia gravis for ten years. She received a total of 180 mg. of neostigmine bromide a day, distributed over the waking hours, taken in three hourly intervals, 25 mg. of ephedrine sulfate once a day, and 1 gram of potassium chloride three times a day. While on this medication, she was able to rise from her bed and to sit by it in an armchair. She was barely able to walk very short distances when aided by an attendant. She had ptosis of the left eye-lid; her extraocular movements were limited in all directions. She also exhibited marked weakness and easy fatigability of the muscles of the palate, tongue, deglutition, chewing, face, and extremities. In addition, she had severe anorexia.

Patient H. L., a 24 year old woman, had had myasthenia gravis for four years. She received a total of 300 mg. of neostigmine bromide a day, distributed over the waking hours, taken in three hourly intervals, 25 mg. of ephedrine sulfate three times a day, 1 gram of potassium chloride three times a day, and 0.13 gram of guanidine hydrochloride three times a day. When on this medication, she was able to walk but showed severe general weakness, ptosis of the right eye-lid, and serious difficulty in swallowing. She had marked muscle weakness and easy fatigability of the muscles of the palate, tongue, deglutition, chewing, face, and extremities. There were periods when general weakness was much intensified and walking became almost impossible. She had anorexia.

Patient M. Y., a 31 year old woman, had had myasthenia gravis for nine years. Removal of the thymus in 1942 was followed by only a temporary remission. The patient received the total amount of 150 mg. of neostigmine bromide a day, distributed over the waking hours, taken in three hourly intervals. No other medication was taken. When on this medication, she was able to walk and do light housework. She exhibited general muscle weakness and easy fatigability, ptosis of one eye-lid, marked weakness of the muscles of the tongue, deglutition, chewing, palate, face, and arms. When speaking she held up her chin with her hand. She had anorexia.

adrenocorticotrophic hormone in the manner described above. The results support in general the inferences of this study.

Patient A. S., a 37 year old woman, had had myasthenia gravis for 13 years. She received a total of 112 mg. of neostigmine bromide a day, distributed over the waking hours, taken in three hourly intervals. No other medication was taken. When on this medication she was able to walk and to do light housework. She exhibited marked general muscle weakness and easy fatigability. She had ptosis of the left eye-lid. She also exhibited weakness of the muscles of the palate, tongue, deglutition, face, arms, and mainly the legs. She had moderate anorexia.

Patient J. R., a 29 year old woman, had had myasthenia gravis for 17 years. She received a total of 45 mg. of neostigmine bromide a day, distributed over the waking hours, taken in six hourly intervals, and 25 mg. of ephedrine sulfate. When on this medication she was able to walk and to do light housework. She exhibited weakness of her leg muscles, moderate weakness of the muscles of the face, and ptosis of the left eye-lid.

During the three years before this special study began the patients experienced minor transient fluctuations but no long lasting or significant changes in their clinical states.

METHOD

The five patients were permitted to take known amounts of neostigmine bromide, and, if already receiving it, other medications. Throughout the study the patients were encouraged in any spontaneous attempts to reduce the amounts of the medications taken. The patients were warned against expecting improvement of their symptoms as a result of the injections received.

Upon admission to the hospital, electromyographic and myographic studies were performed once a day approximately at the same time of the day. After a one week period of observation each patient received by intramuscular injections 20 mg. of the adrenocorticotrophic hormone (Armour) every six hours for five days. Tests were performed during the administration of the hormone and afterwards until the writing of this report (approximately three months).

Controls. Ten healthy women aged from 27 to 44 years served as controls.

Electromyography

Records of muscle action potential were taken from healthy women and from patients with myasthenia gravis by the following method (6, 7): The forearm was firmly fixed in the supine position onto a padded board by means of broad straps placed across the arm near the elbow and the wrist. Of the two silver recording electrodes (0.5 sq. cm.), one was fixed with adhesive tape to the skin over the ventral surface of the first phalanx of the fifth finger and the other over the surface of the hypothenar eminence at a distance of about 5 cm. from the first electrode. The electrodes were connected to the grid terminals of an amplifier feeding into an oscilloscope. The stimulating electrodes consisted of two silver plates, the larger being affixed to the skin over the triceps

muscle and the smaller, a movable electrode 0.5 cm. in diameter, being pressed firmly against the skin over the ulnar nerve just above the elbow. Good contact was established by the use of electrode jelly over the skin, which was partially deprived of its superficial epidermis. Ten and 30 pulses per second, each of 100 microseconds' duration and of "supramaximal" intensity, were administered for two minutes. The sweep circuit of the oscilloscope was synchronized with the stimulator so that successive stimuli and muscle action potentials were superimposed on the screen of the cathode ray tube. The action potential was recorded photographically.

Electromyograms were recorded for seven days before administration of the hormone, the five days during administration of the hormone, four days after completion of the series of administrations of the hormone, and at biweekly intervals thereafter. The records were taken at the same time of the day, three hours after the administration of neostigmine bromide before and during administration of the hormone, and from six to 15 hours after administration of neostigmine bromide after completion of the series of administrations of the hormone.

Myography

Muscle function was also tested by an ergograph. The ergograph consisted of a heavy spring attached to an isotonic lever writing on a kymograph. The spring was stretched 2.5 cm. once a second by the index and middle finger of the right hand exerting a tension of 15 kg. until fatigue occurred. The patients with myasthenia gravis performed the test once a day for a week before the period of administration of the adrenocorticotrophic hormone, during the five days of administration, and for four days after completion of administration of the hormone. Thereafter, the test was performed biweekly. The myograms were recorded immediately after completion of the electromyograms.

Biochemical studies (Acetylcholine Synthesis)

Acetylcholine synthesis in the presence of serum was studied following the method described by Torda and Wolff (2) before the injection period of the hormone, the third day after completion of the injection period, and biweekly thereafter. The method consists of incubation of a tissue containing choline acetylase with blood serum and determination of the amount of acetylcholine formed during the period of incubation.

RESULTS

General observations

During the five days of administration of the adrenocorticotrophic hormone the patients experienced a gradually increasing disability lasting until the second day after the end of the series of injections. This disability consisted of malaise, headache or "heaviness of the head," disturbance

in the menstrual cycle (bleeding), slightly increased fatigability, occasional diarrhea, abdominal cramps, and complaints of hot feet and hands.

On the second or third day after the last injection of the adrenocorticotrophic hormone the situation changed: the patients exhibited and described increasing well being and began to reduce the daily intake of neostigmine bromide and the other agents. Patient H. L. reduced the total of 300 mg. of neostigmine bromide a day to 45 mg. and omitted the other medications; patient M. Y. reduced the total daily intake of neostigmine bromide from 150 mg. to 15 mg.; patient A. S. reduced the total daily intake of neostigmine bromide from 112 mg. to 22.5 mg.; patient R. G. reduced the total daily intake of neostigmine bromide from 180 mg. to 90 mg.; and patient J. R. reduced the total daily intake of neostigmine bromide from 45 mg. to 15 mg. Also, more visible and measurable changes occurred in the patients that might indicate the beginnings of a partial remission. Thus, there was a clearly evident improvement of the facial muscle strength, the general muscle weakness and easy fatigability diminished, and the ptosis of the eye-lids was less evident. Difficulty in swallowing diminished significantly and the patients were able to hold heavy objects in their hands for a period of time. The appetite for food increased. However, in all instances the remission was incomplete. The muscle groups most severely involved (*i.e.* extraocular muscles and leg muscles in patient R. G., muscles of the forearm and foot in patient H. L., some muscles involved in chewing in patient M. Y., leg muscles in patients A. S. and J. R.) showed only partial recovery of function. This improved neuro-muscular function persisted from the completion of administration of the adrenocorticotrophic hormone to the writing of this report (approximately three months).

Electromyography

Healthy subjects maintained the muscle action potential during indirect stimulation with ten pulses per second for two minutes unaltered (13, 14) (Figure 1A). The action potential decreased on the average 12 per cent during indirect stimulation with 30 pulses per second for two minutes.

FIG. 1. EFFECT OF ADRENOCORTICOTROPHIC HORMONE ON MUSCLE ACTION POTENTIAL DURING REPETITIVE INDIRECT STIMULATION WITH TEN PULSES PER SECOND (PERCUTANEOUS STIMULATION OF THE ULNAR NERVE)

A. Muscle action potential of a control subject:

1. Taken during the first few pulses of a 30 second stimulation period;
2. Taken at the end of the 30 second stimulation period; the action potential was maintained unchanged.

B. Muscle action potential of patient H. L.:

1. Taken during the first few pulses of a 30 second stimulation period before administration of the hormone;
2. Taken at the end of the 30 second stimulation period; the action potential decreased during the first few pulses of stimulation and was maintained at the new level thereafter;
3. Taken during the first few pulses of a 30 second stimulation period the third day after completion of the series of administrations of the hormone;
4. Taken at the end of the 30 second stimulation period; the action potential was maintained unaltered.

C. Muscle action potential of patient M. Y.:

1. Taken during the first few pulses of a 30 second

stimulation period before administration of the hormone;

2. Taken at the end of the 30 second stimulation period; the action potential decreased during the first few pulses of stimulation and was maintained at the new level thereafter;
3. Taken during the first few pulses of a 30 second stimulation period the third day after completion of the series of administrations of the hormone;
4. Taken at the end of the 30 second stimulation period; the action potential was maintained unaltered.

D. Muscle action potential of patient A. S.:

1. Taken during the first pulse of a 30 second stimulation period before administration of the hormone;
2. Taken at the end of the 30 second stimulation period; the action potential decreased during the first few pulses of stimulation and was maintained at the new level thereafter;
3. Taken during the first pulse of a 30 second stimulation period the third day after completion of the series of administrations of the hormone;
4. Taken at the end of the 30 second stimulation period; the action potential was maintained unaltered.

E. Muscle action potential of patient R. G.:

1. Taken during the first few pulses of a 30 second stimulation period before administration of the hormone;
2. Taken at the end of the 30 second stimulation period; the action potential decreased during the first few pulses of stimulation and was maintained at the new level thereafter;
3. Taken during the first few pulses of a 30 second stimulation period three months after completion of the series of administrations of the hormone;
4. Taken at the end of the 30 second stimulation period; the action potential remained unaltered.

F. Muscle action potential of patient J. R.:

1. Taken during the first few pulses of a 30 second stimulation period before administration of the hormone;
2. Taken at the end of the 30 second stimulation period; the action potential was maintained within normal limits.
3. Taken during the first few pulses of a 30 second stimulation period the third day after completion of the series of administrations of the hormone;
4. Taken at the end of the 30 second stimulation period; the action potential remained unaltered.

Since the recording electrodes were not moved during the 30 second stimulation period the action potentials of columns 1 and 2 and columns 3 and 4 are comparable. Since the recording electrodes could not be placed in exactly the same position on successive days the action

potentials in column 1 are not comparable with those in column 3.

In all records the sweep circuit of the oscilloscope was synchronized with the stimulator so that successive stimuli and muscle action potentials were superimposed on the screen of the cathode ray tube.

In patients severely ill with myasthenia gravis the muscle action potential in affected muscles rapidly decreased during repetitive indirect stimulation (13, 14). Thus, before administration of the adrenocorticotrophic hormone, the action potential of patients H. L., M. Y., R. G., and A. S. decreased during the first few seconds of stimulation and was maintained at the new amplitude during continuation of the stimulation for two minutes. There was a considerable daily variation in the decrease in the amplitude of the muscle action potential. The decrease of the action potential was, however, in all instances over 35 per cent with 10 pulses per second and over 55 per cent with 30 pulses per second (Figure 1B-1F). The muscle action potential in patient J. R. was similar to the action potential of healthy controls, as is always the case in patients moderately or mildly ill with myasthenia gravis (13).

After completion of administration of the adrenocorticotrophic hormone and while on reduced medication the patients maintained the action potential during repetitive indirect stimulation with 10 and 30 pulses per second in a manner approximating that of healthy subjects (Figure 1B-1F). At the time of writing this report, approximately three months after completion of the administration of the hormone, the action potential was still maintained in a manner approximating that of healthy subjects.

Myography

The patients were trained for a few days in the use of the ergograph during the preliminary period of observation. The amount of work performed varied daily. The average number of contractions were, however, far below the average number of contractions of control subjects, except with patient J. R. The average number of contractions before occurrence of fatigue was 31 in patient R. G., 44 in patient A. S., 47 in patient M. Y., 75 in patient H. L. and 110 in patient J. R. The average of the ten healthy controls was 150.

During the period of administration of the adrenocorticotrophic hormone the number of contractions slightly and gradually increased. After completion of administration of the adrenocorticotrophic hormone the work performance continued to increase. The number of contractions increased from the first to the fifth day after completion of the series of administrations of the hormone. The average number of contractions during the first four days after completion of administration of the hormone was 98 in patient R. G., 120 in patient A. S., 165 in patient M. Y., 233 in patient H. L., and 160 in patient J. R. The increase in performance was maintained at the time of writing of the present report (approximately three months) (Table I). Although this test in-

volves motivation, a sudden and dramatic increase in performance suggests an improvement of the function of the neuro-muscular system per se.

Biochemical studies (Acetylcholine synthesis)

The synthesis of acetylcholine in the presence of body fluids (1-3) from patients with myasthenia gravis is decreased, suggesting that the body fluids contain in excess substances that inhibit the activity of choline acetylase. The more severe the myasthenia gravis the less well the blood serum supports the activity of choline acetylase.

In the presence of blood serum from patients with myasthenia gravis before administration of the adrenocorticotrophic hormone the synthesis of acetylcholine decreased 25 to 55 per cent (Table II). In the presence of blood serum taken the third day following completion of the series of administrations of the hormone and biweekly thereafter until writing of the present report (approximately three months) the synthesis of acetylcholine greatly increased and became similar to that occurring in the presence of serum from healthy subjects (Table II). The amount of acetylcholine synthesized in the presence of serum from the controls averaged $2.08 \mu\text{g} \pm 7$ per cent per 100 mg. tissue containing choline acetylase.

GENERAL COMMENT

Administration of the adrenocorticotrophic hormone of the pituitary gland to patients with myasthenia gravis was first begun in 1944 by Torda and Wolff (5, 20). A partial remission consisting essentially in the ability to perform more work while taking significantly reduced amounts of medication occurred in the two patients with myasthenia gravis treated with the hormone. Because satisfactory objective procedures testing neuro-muscular function per se had not been elaborated in this laboratory at the time and since spontaneous remissions and improved motivation make evaluation of clinical changes difficult, inferences concerning the effect of the adrenocorticotrophic hormone in patients with myasthenia gravis were deferred.

In 1948 Soffer and collaborators (21) using no objective testing procedures of the neuro-muscular function reported a remission of the symptoms of

myasthenia gravis in a moderately ill woman after administration of the adrenocorticotrophic hormone.

Hellman (22) reported an augmentation of the symptoms of patients with myasthenia gravis as a result of administration of the adrenocorticotrophic hormone. However, this impairment seems to have occurred during the period of injection with the hormone, an effect also noticed in the patients of the present study. Decrease in symptoms in the latter patients was evident only after the second day following the last injection of the hormone.

Increased general disability during the period of administration of the adrenocorticotrophic hormone may result from the sudden changes in many phases of metabolism. Some of these are a decrease of the glutathione content of blood (23, 24), a sudden increase of the secretion of many steroid hormones (23-28), an adverse effect on carbohydrate metabolism, and disturbances in the

remission, although incomplete, was sudden in onset, was significant and long lasting, encouraging the inference that administration of the hormone and the occurrence of the remission were causally related. Remission must be, by the nature of the disorder, incomplete, since after patients with myasthenia gravis have had muscle dysfunction for some years, as was the case in the patients of this study, irreversible structural changes in muscle probably occur. Even assuming that regeneration under suitable conditions may ultimately take place, such regeneration would not exhibit itself in a short time.

If the view suggested by this laboratory be valid, *i.e.*, that the immediate cause of the symptoms of patients with myasthenia gravis is a decrease in the synthesis of acetylcholine (1-4) then the observation that administration of the adrenocorticotrophic hormone increases the synthesis of acetylcholine (5) becomes extremely pertinent to an understanding of the apparent remission of symptoms observed in patients with myasthenia gravis after administration of the adrenocorticotrophic hormone.

TABLE II

electrolyte balance within the body (26). All of these changes impede the synthesis of acetylcholine (20, 29-31) and augment the symptoms of patients with myasthenia gravis (20). A decrease of symptoms in patients with myasthenia gravis studied at the New York Hospital in 1945 followed an experimentally induced (20) increase of the "reduced-glutathione" content of the body. The remission observed after administration of the adrenocorticotrophic hormone began a few days after the completion of the injections. The

SUMMARY

1. The adrenocorticotrophic hormone of the pituitary gland has been administered to five patients moderately to severely ill with myasthenia gravis.

2. Before administration of the adrenocorticotrophic hormone the patients exhibited the known decline of the amplitude of muscle action potential during repetitive indirect stimulation. Also, the amount of work performance on an ergograph averaged only 30 per cent of that performed by healthy subjects selected from the same sex and from similar age group as were the patients. The amount of acetylcholine synthesized in the presence of blood serum of the patients was below normal.

3. Four hundred mg. of the adrenocorticotrophic hormone were administered in 20 mg. amounts every six hours. During the period of administration the patients experienced an increase in disability. The second day after completion of the series of injections the patients experienced changes suggesting the beginnings of

an incomplete remission of the disorder. This consisted of marked improvement of muscle function while on appreciably reduced neostigmine bromide. The much reduced ability of blood serum to support acetylcholine synthesis returned to normal. Furthermore, the electromyogram and myogram became similar to those of healthy subjects. This incomplete remission precipitated by the adrenocorticotrophic hormone persisted for an, as yet, undefined period.

ACKNOWLEDGMENT

The authors wish to express their gratitude to Dr. John R. Mote, Medical Director, Armour Laboratories, Inc., for the generous supply of the adrenocorticotrophic hormone.

The electrical equipment was constructed by Grass Instrument Company.

THE SERUM PROTEINS IN PORTAL CIRRHOSIS UNDER MEDICAL MANAGEMENT. ELECTROPHORETIC STUDIES¹

By KENNETH STERLING,² WILLIAM E. RICKETTS, JOSEPH B. KIRSNER,
AND WALTER L. PALMER

(From the Frank Billings Medical Clinic, Department of Medicine, The University of Chicago, Chicago, Ill.)

(Received for publication May 9, 1949)

Alterations in the composition of the serum proteins in hepatic disease have been studied by numerous workers using the electrophoretic method (1-11). The present investigation was undertaken to determine the changes in the serum proteins in portal cirrhosis by serial electrophoretic analyses during the course of prolonged medical management.

METHODS

Electrophoretic runs were performed with standard apparatus and technique, the experimental details having been given in an earlier report (11). The tests of hepatic function were performed by the usual methods as previously described (11), alkaline phosphatase being reported in Bodansky units.

CASE MATERIAL

The ten cases of the present study were all chronic alcoholics considered to have proven portal cirrhosis. The diagnosis was confirmed histologically by Vim-Silverman needle biopsy of the liver in seven of the ten cases, and in one patient (R. M. S.) also by autopsy. In one case (P. F.) the cirrhotic liver was visualized by peritoneoscopy and subsequently during an umbilical herniorrhaphy, but tissue for biopsy was not obtained. In two clinically typical cases (J. H. and C. R.), needle biopsy was attempted, yielding minute amounts of fibrous tissue considered insufficient for histologic diagnosis.

The ten cases were divided into two groups.

Group I. Five patients with hepatic insufficiency and ascites were studied with serial electrophoretic analyses of the serum proteins and various tests of hepatic function during the course of medical management for periods ranging up to ten months.

The initial electrophoretic analysis designated as "Day 0" was carried out before or very early in the course of medical management. Although a few patients had re-

¹This investigation has been made with the assistance of a grant from the Committee on Therapeutic Research, Council on Pharmacy and Chemistry, of the American Medical Association.

²Present address: Department of Medicine, Harvard Medical School, Boston, Mass.

ceived some form of therapy elsewhere prior to study, with one exception none had followed an adequate dietary regime for any appreciable period.

Group II. Five patients were studied after sustained clinical recovery under medical management. These individuals had been severely ill with hepatic insufficiency; ascites requiring paracenteses had been present in four, and pronounced jaundice in one. With treatment they had clinically recovered and had remained asymptomatic for more than two years.

THERAPEUTIC REGIME

The basic therapeutic regime consisted of a diet high in protein, carbohydrate and calories, containing 120 to 150 grams of protein, 350 to 450 grams of carbohydrate, a total of 3000 to 3500 calories, supplemented by 4 to 6 grams of choline chloride per day. The intake of sodium was restricted to 500 mg. per day in the patients in Group I as long as clinical evidence of ascites remained. The dietary regime was rigidly enforced during the hospital stay; after discharge patients were strongly urged to adhere to the diet, and were closely followed with numerous clinic visits. Not more than one paracentesis was done on any patient during the study; mercurial diuretics were used infrequently.

Other measures such as infusions of plasma or human albumin were employed as noted below. Salt-poor, concentrated human albumin was given as a 25% solution by slow intravenous infusion.

RESULTS

Group I. The initial electrophoretic analyses (Day 0) disclosed marked diminutions of the albumin fractions and elevations of the gamma-globulin fractions; the beta-globulins were somewhat less elevated (*cf.* normal serum, Figure 6 and Table VI).

J. K.—51 year old male. Hematemesis and melena occurred after an alcoholic debauch of two weeks' duration. On admission the patient had very severe jaundice, edema and ascites. Complete clinical recovery with subsidence of jaundice and disappearance of ascites occurred after three months of treatment. The patient remained free

PORTAL CIRRHOSIS UNDER MEDICAL MANAGEMENT

J.K. - 51 year old male. Chronic alcoholic. Hematemesis and melena, extreme jaundice, ascites with paracentesis. Complete clinical recovery with disappearance of ascites on dietary regime.

improved only partially, and after discharge from the hospital did not adhere to the diet. The ascites disappeared in one month, but the jaundice persisted during the subsequent five months of observation.

The electrophoretic patterns (Figure 2 and Table II) revealed pronounced evolution toward normal (fully as marked as in J. K.). The last pattern on *Day 140*, however, was appreciably abnormal.

M. S.—56 year old female. Jaundice had been present for six months; the patient was admitted to the hospital three weeks after the onset of ascites and edema of the ankles. On the dietary regime partial clinical recovery ensued during a period of five months, with subsidence of jaundice and ascites; the improvement was maintained during five additional months of observation, although the patient had not fully regained her usual vigor and sense of well-being.

PORTAL CIRRHOSIS UNDER MEDICAL MANAGEMENT

M.S. - 56 year old female. Chronic alcoholic. Jaundice and ascites. Partial clinical recovery with disappearance of ascites on dietary regime.

FIG. 3

The serial electrophoretic patterns (Figure 3 and Table III) indicated a very gradual change in the direction of normal, but after the relatively asymptomatic period of five months, the pattern still remained markedly abnormal with a pronounced elevation of the gamma-globulin fraction (Day 304).

R. M. S.—43 year old male. Manifestations

of cirrhosis had been present for more than two years with spider angiomas, episodes of jaundice, melena, edema and ascites necessitating paracentesis. Prior to admission, the patient had received elsewhere plasma, choline, and Vitamin K, as well as dietary treatment. The ascites disappeared after medical management including plasma infusions (3000 cc. in nine days). Just

been eating before hospitalization. Partial clinical improvement occurred, with slight diminution of ascites. There was almost 1 gram per cent rise in the total proteins, but relatively little change toward normal in the proportions of the fractions as determined by five electrophoretic analyses (Figures 5a and 5b, and Table V). Experiments on electrolyte and water metabolism (to be reported separately) were performed during this period with no significant effect on the electrophoretic pattern.

In the 12-day period of Day 87 through Day 98 while on the "regular" diet, the patient received 8000 cc. of plasma. The electrophoretic pattern of Day 105 revealed for the first time a considerable change toward normal.

From Day 108 on the patient was on the full dietary regime (C 437, P 155, F 123, Cal. 3475 supplemented by 5 grams choline chloride). In the ten-day period of Day 126 through Day 135 he received 3600 cc. of whole blood. There was no further change of the electrophoretic pattern toward normal (Day 136 and Day 165), but on the contrary, some retrogression.

The intravenous administration of 300 grams of salt-poor concentrated human albumin in six days (Day 166 through Day 171) was followed by a striking elevation of the serum albumin in the electrophoretic pattern of Day 172, while both the relative and absolute values of all globulin fractions were diminished, presumably due to dilution. Three days later (Day 175), the electrophoretic pattern revealed some decline of the serum albumin and rise of the gamma-globulin and other globulin fractions.

After a second course of 300 grams of salt-poor concentrated human albumin, administered in three days (Day 175 through Day 177), a striking elevation of the serum albumin and a diminution of all the globulin fractions again occurred. Once more this was followed by some decline of the serum albumin and a rise of the gamma-globulin and other globulin fractions, this trend being clearly evident in the patterns of Days 182, 192, and 241, respectively five, 15, and 64 days after the last infusion of albumin. The ascites disappeared and the patient was discharged on Day 192 completely free of clinical symptoms, and he resumed

his former occupation. A partially strangulated umbilical hernia was repaired on *Day 212* with uneventful recovery. In spite of this episode the final electrophoretic analysis of *Day 241* indicated a higher absolute value for serum albumin than at any time prior to institution of the human albumin therapy, and a higher total protein than at any time. Six months after the last albumin infusion the patient remained well, having gained weight with no recurrence of edema or ascites.

Group II. The five cases of portal cirrhosis with long-term clinical recovery under medical management are summarized briefly in Figure 6. The patients had been severely ill with hepatic insufficiency before treatment; four had ascites requiring paracenteses and one had pronounced jaundice; all had hypoalbuminemia, the mean of the albumin values of the five patients being 2.58 grams per cent by Howe sodium sulfate fractionation. As illustrated in Figure 6 and Table VI, the electrophoretic patterns after sustained re-

covery appear very nearly normal with but minimal deviations from the normal range.

DISCUSSION

The five patients in Group I initially had marked diminutions of the albumin fractions and elevations of the gamma-globulin fractions, with somewhat less elevated beta-globulins. During the course of medical management the serum proteins underwent progressive evolution in the direction of normal, coinciding with clinical improvement. The progress of the three patients in the group treated with diet alone indicates that this is not a perfectly strict relationship. J. B., who improved only partially (the ascites disappearing, but the jaundice persisting), had fully as pronounced a change of the electrophoretic pattern toward normal as did J. K. with complete clinical recovery. Moreover, M. S., whose clinical improvement was more marked than J. B.'s, had less evolution toward a normal serum protein composition, the

gamma-globulin fraction remaining markedly elevated.

The two cases in Group I considered to have achieved complete clinical recovery, J. K. and P. F., continued to have appreciable abnormalities in the serum protein composition. That the serum protein composition may eventually become normal or nearly so in cases with long-term clinical recovery under medical management is indicated by the five patients in Group II (Figure 6). At the time of admission with hepatic insufficiency these patients all had marked alterations of the serum proteins by the Howe fractionation, which is less sensitive than the electrophoretic technique.

The evaluation of changes in the serum proteins in edematous patients is hazardous unless account is taken of the possibility of shifts in body fluids. Thus an increase in protein concentration may reflect either an increase in the circulating protein or a decrease in the volume of the plasma.

During the observation of P. F., 16 estimations of the plasma volume were made with Evans blue.

to be reported separately in connection with studies of electrolyte metabolism. The findings did not indicate that changes of plasma volume would account for the progressive rise of total proteins on dietary therapy or infusions.

In J. K., J. B., and M. S., the three cases treated by diet without infusions, the electrophoretic data alone exclude the possibility that the rise in albumin and total proteins could be solely due to hemoconcentration. These three cases exhibited rise of albumin and decline of gamma-globulin, a circumstance not explicable in terms of any possible fluid shift, and indicating changes in protein metabolism.

In the infusion experiments it appears probable that transitory changes in plasma volume did play a role. The infusion of plasma was followed by increases in the albumin and the beta- and gamma-globulin fractions as well as the total proteins. The *immediate* effects of intravenous administration of salt-poor concentrated human albumin on the serum protein composition were

identical with those observed by Thorn, Armstrong, and Davenport (6), *i.e.*, marked elevation of the albumin and depression of the globulin fractions; presumably due to dilution. The changes beginning shortly thereafter consist of some decline of the albumin and rise of the gamma-globulin and other globulin fractions. These ensuing alterations have apparently not been described by previous investigators of human albumin infusion therapy. The phenomenon was observed in the two administrations of human albumin to P. F. and also in a patient with cirrhosis of uncertain etiology not included in the present study. The significance of these observations remains to be determined. It is possible that as the administered albumin left the circulation the plasma volume decreased with resultant concentration of the globulin components.

Comparison of the alterations of the serum proteins with the various tests of hepatic function performed simultaneously fails to reveal any clearly evident direct correlation.

SUMMARY

1. The effects of medical management on the serum proteins in ten proven cases of portal cirrhosis have been investigated by the electrophoretic method.

2. Serial electrophoretic analyses of the sera of patients with ascites revealed progressive change in the direction of normal, coinciding with clinical improvement during the administration of a high protein, high carbohydrate, high caloric diet for periods ranging up to ten months.

3. Infusions of plasma or salt-poor concentrated human albumin were followed by pronounced and immediate elevations of the serum albumin values.

4. Shortly after the administration of human albumin, some decline of the elevated albumin value was observed, with rise of the gamma-globulin and other globulin fractions.

5. In five patients who had clinically recovered from severe portal cirrhosis and had been asymptomatic for more than two years the electrophoretic patterns were very close to normal.

6. The alterations in the serum protein pattern in portal cirrhosis are not irreversible; with prolonged medical management and clinical recovery, the proteins may revert practically to normal.

The authors wish to express their gratitude to Doctor E. S. Guzman Barron for making available the electrophoretic apparatus used in this study.

Kolmer's CLINICAL DIAGNOSIS BY LABORATORY EXAMINATIONS

By John A. Kolmer, M.D., F.A.C.P.

This completely revised edition presents the interpretation and application in relation to diagnosis of medical laboratory tests and examinations. It is based on our present knowledge of hematology, biochemistry, toxicology, bacteriology, virology, mycology, serology, endocrinology and parasitology.

New 3rd Edition

FUNDAMENTALS OF INTERNAL MEDICINE

By Wallace M. Yater, M.D., F.A.C.P.

WITH THE COLLABORATION OF

J. C. Adams, Garnet W. Ault, Joseph M. Barker, Grafton T. Brown, Edward J. Cummings, Harold L. Hirsh, Hugh H. Hussey, Jr., Paul F. Jaquet, Jr., Francis R. Keating, Jr., Norman L. Barr, Isadore Rodis, Sanford M. Rosenthal, Walter O. Teichmann, Frederick C. Schreiber, W. H. Sebrell and
Jonathan M. Williams

In preparing this completely revised and reset edition the authors have retained its characterizing features of simplicity and conciseness with the elimination of theoretical and redundant material. General practitioners and students will profit from the inclusion of practical sections of diseases of the skin, ear and eye in addition to concise sections on dietetics, chemotherapy, antibiotic therapy, symptomatic and supportive treatment, inhalation therapy, and electrocardiography. Numerous and excellent illustrations supplement the text material.

1451 Pages. 315 Illustrations. \$12.00

PRODUCTION AND AVAILABILITY OF RADIOISOTOPES

By PAUL C. AEBERSOLD

(From the Isotopes Division, U. S. Atomic Energy Commission, Oak Ridge, Tenn.)

Radioisotopes as tracer atoms and as uniquely applicable sources of radiation have become important working tools of clinical investigation. Indeed, they have already been established as permanent tools, indispensable to many investigations. They provide a new and dynamic power of perception—an ultra-sensitive way of following certain atoms. Their application has led to the development of new and unique techniques for studying the metabolism of a wide variety of elements and biochemical compounds, diagnosing and treating disease and studying the behavior and role of pharmaceuticals and other medicinal agents. However, the greatest value of isotopes is expected to be derived from their contribution to the over-all advance of medical knowledge.

PRODUCTION

The uranium chain-reacting pile has two unique characteristics, the production of a fission chain reaction and the production of vast quantities of neutrons. Both of these features make the reactor a useful and extremely productive unit for making radioisotopes; the first for yielding the so-called "fission products," and the second for producing artificially induced radioactivity. It is the second feature, however, which permits the production of the greater variety of radioelements and the production of isotopes of elements generally found in biological material.

Even before the last war and before the advent of atomic energy reactors, radioisotopes were, of course, producible with high energy "atom smashing" devices, such as the cyclotron. Indeed, investigators using cyclotron-produced isotopes had found in them the most sensitive tool ever placed at their disposal. They also found the radioisotope to be a tool which will permit tracing a specific batch of atoms through a complicated physical, chemical or biological system even though the radioactive atoms may become mixed with many other stable atoms of the same element.

There was one drawback, however, to their widespread utilization at that time. Cyclotron production of radioisotopes was and still is both

limited and costly. Thus at the start of the war, science had in radioisotopes a research tool guaranteeing high sensitivity and high specificity—a tool in great demand but in small availability.

During the wartime development of the atomic energy project it became evident to scientists who worked with the chain-reacting uranium pile that it would be an excellent unit for producing huge quantities of radioactivity or radioisotopes—for making these valuable tools available on a very wide scale. Out of this realization grew the program for the distribution of pile-produced radioisotopes which was initiated by the Manhattan Project and further developed by the Atomic Energy Commission.

As indicated earlier, radioactive isotopes are created in chain-reacting piles by two processes (1) fission of uranium 235 or other fissionable nuclei and (2) neutron absorption by non-fissionable nuclei placed in the pile for the purpose.

Fission Process

The fission process results generally in two radioactive fragments, one to three neutrons and several gamma rays as indicated in Figure 1. The total mass of the fragments plus the mass of the one to three neutrons which are emitted during the fission event is equal to the mass of the U 235 nucleus (except for the loss of about one-tenth of 1 per cent of the mass which is converted into energy and which causes the tremendous release of energy during fission). The fission fragments are very unstable nuclear species ranging from element number 30, zinc, to element number 64, gadolinium. Each of these species approaches a stable nuclear state by a series or chain of beta ray emissions. The intermediate decay products formed during the beta chain decay are the fission products.

These fission products, because they differ chemically from the original uranium and other possible transuranic contaminants, may be isolated in groups or as isotopes of a single element. The only radioisotope of biological significance produced in this way, however, is radioiodine, I^{131} .

URANIUM FISSION AND BETA CHAIN DECAY

FIG. 1. URANIUM FISSION CHAIN REACTION

When Uranium 235 fissions it splits into two fragments which may range in weight from 65 to 157 or from element number 30, zinc, to element number 64, gadolinium. On the basis of probability, however, a greater percentage of the fragments range from element number 38 to 45, and from number 54 to 61. Each of the radioactive fragments approaches a stable nuclear state by a series or chain of beta ray emissions. The intermediates formed during this decay are the source of the fission products, such as radioiodine 131. Although the above illustration shows only one of many ways in which a $\text{U } 235$ atom may fission, it was chosen as a single example in which a conservation of mass and number of nuclear particles can be shown. It is also an excellent example of how a biologically useful radioisotope, iodine 131, may be produced through uranium fission.

The production of radioiodine as a fission product is shown in Figure 1.

Neutron Activation

The pile production process which yields radioisotopes of a much wider variety of elements, in fact, radioisotopes of most of the elements from hydrogen to plutonium, is neutron absorption. Generally, however, the neutron absorption process is subdivided into two categories: (1) simple neutron capture in which only a gamma ray photon is emitted and the product is hence an isotope of the target element and (2) transmutation in which

a proton or alpha particle is emitted and the product is hence an isotope of a different element than the target.

The neutron absorption process of making radioisotopes in the pile is extremely prolific because of the pile's capacity to produce tremendous quantities of neutrons. Indeed, neutrons can be produced greatly in excess of those needed to sustain the chain reaction, and these excess neutrons are available for other uses, such as the bombardment of stable materials to form radioactive materials. In the pile at the Oak Ridge National Laboratory where most of the radioisotopes distributed by

the Atomic Energy Commission are prepared, the "flux" or density of the "atmosphere" of neutrons inside the pile is approximately 10^{12} (a million million) neutrons flowing through a square centimeter each second. This value seems even more impressive when one considers that this density exists in a volume occupied by many tons of graphite and uranium.

For the details of production of radioisotopes by neutron absorption, attention is called to Figure 2. As indicated in the illustration, ordinary elements like carbon and phosphorus may be changed

into their radioactive counterparts by the absorption of a neutron and the emission of a photon of gamma radiation. This reaction, usually referred to as an (n, gamma) reaction, is by far the most prevalent production reaction used in radioisotope preparation. It is not, however, the most practical in all cases. For instance, in the production of radioactive carbon 14 by the (n, gamma) reaction, a neutron must be absorbed by the stable isotope, carbon 13. Although carbon 13 is found in all naturally occurring carbon, it has a normal abundance of only 1.1 per cent. To obtain an efficient yield of carbon 14 by this method would therefore necessitate bombarding a carbon target whose carbon 13 content had been concentrated many times above this abundance. This procedure would, however, prove time-consuming and expensive. Furthermore, it is even less feasible in light of the fact that the carbon 13 isotope has an extremely low probability for capture of "slow" or thermal energy neutrons (low neutron capture cross section). With radioactive phosphorus 32, however, the situation is quite different, in fact the (n, gamma) reaction is very practical for its production. Because naturally occurring phosphorus has only one stable isotope (phosphorus 31) and because this isotope has a high probability for capturing thermal energy neutrons, a good yield of radioactive phosphorus results from the (n, gamma) reaction.

The radioisotope formed by an (n, gamma) reaction is merely the radioactive counterpart of the stable element used as the target material. The radioisotope in this case, therefore, will always be diluted with the stable atoms of the target element which have not been made radioactive during the pile irradiation. Because both the radioactive and stable atoms are of the same element, no chemical separation can be effected. The resultant activity per gram of element is called the "specific activity." It is dependent on the chance for capture of a neutron (capture cross section) by the target nucleus, the neutron "flux" of the production pile and the duration of the irradiation. The specific activity of a radioisotope may be extremely important for its use as a tracer because it determines to what extent the radioisotope may be diluted and still afford reliable detection and measurement.

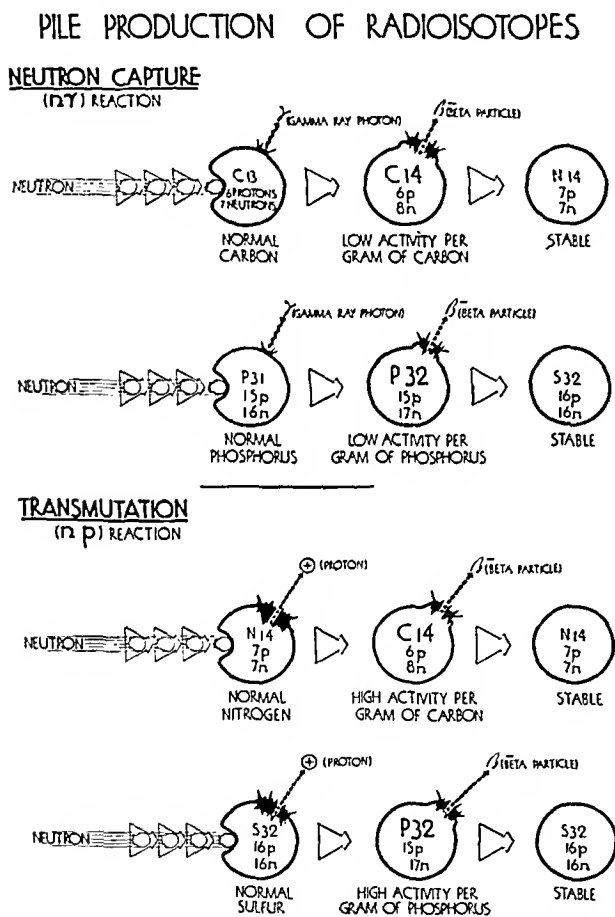

FIG. 2. PILE PRODUCTION OF RADIOISOTOPES

There are two ways of producing radioisotopes by neutron absorption in a nuclear reactor. The first, neutron capture, is effected by the capture of a neutron and the emission of a gamma ray photon yielding a radioisotope of the same element as the target material. The second, transmutation, is effected by the capture of a neutron and the emission of a proton or alpha particle yielding a radioisotope non-isotopic with the target element. Radiophosphorus 32 and radiocarbon 14 may be produced by either or both of these reactions.

On the other hand, a radioisotope produced by a transmutation reaction is an isotope of a different element than the target element (non-isotopic with the target element). It may, therefore, be chemically separated from the residual stable atoms in the target after pile irradiation. A radioisotope produced in this way and then chemically separated from the irradiated material, *i.e.*, from the stable isotopes of the same element, is called "carrier free." In practice some "carrier" or stable element is usually added to facilitate radiochemical handling. Nevertheless, radioisotopes produced by transmutation have a much higher specific activity than those produced by an (n, gamma) reaction. For this reason, transmutation is a particularly useful production reaction. The chemically extracted transmuted radioisotope will be diluted only by stable element present as impurity in the compound irradiated, or by stable element added as carrier to help extract the radioisotope. It can thus undergo great dilution in a tracer experiment before becoming undetectable.

As also indicated in Figure 2, radiocarbon 14 and radiophosphorus 32 may be produced by a transmutation reaction. In both cases a neutron is absorbed and a proton is emitted during the reaction. In the case of carbon 14 production, the target material is a nitrogen compound (calcium nitrate) while for phosphorus 32 the target material is elemental sulfur. Both of these target nuclei have a high natural abundance in the element and both target materials are readily available and may be obtained quite pure chemically.

There is still another type of transmutation reaction used in the pile production of radioisotopes—the reaction in which a neutron is absorbed and an alpha particle is emitted. This reaction, however, is feasible for the production of only two isotopes, radiohydrogen (H 3 or tritium) from lithium 6 and radioargon (A 37) from calcium 40.

The mechanical operations associated with pile production of radioisotopes is quite simple. Reference is made to Figure 3 showing a schematic diagram of the pile at the Oak Ridge National Laboratory which is used to make most of the radioisotopes now being distributed by the Commission. In the case of the fission products, the radioisotopes are chemically extracted from the active uranium slugs which have previously been

discharged into a channel of water at the rear of the pile.

If the radioisotope has resulted from an (n, gamma) reaction, it is usually shipped as an irradiated unit. This means that the material in the aluminum test tube, consisting of stable atoms of the target material together with their counterparts which have been made radioactive, is merely removed and packaged prior to shipping. If, on the other hand, the radioisotope has been produced by a transmutation reaction, it may be chemically separated from the target material prior to packaging and shipping.

Production Status

When the radioisotope distribution program was initiated, production scheduling was based primarily on the expected demand of medical investigators. To a great extent the same basis is used in scheduling current production. At least two reasons account for this situation. In the first place a majority of potential radioisotope users were and still are associated with some phase of medical or biological research. In the two and a half year period since the inauguration of the distribution program, nearly 75 per cent of the radioisotope shipments have been used for studies in medical therapy, animal physiology or bacteriology.

The second reason for special effort in preparing the radioisotopes needed by medical research is associated with the characteristics of the isotopes generally used in these investigations. Many of the biologically useful radioisotopes are short lived materials, that is, over a comparatively short period of time most of the radioactivity of the isotope will have disappeared through spontaneous disintegration. Indeed, if the radioisotope is to be used in human studies, it is desirable that it have a short life of radioactivity in order to prevent extended radiation exposure of the patient. It is difficult, however, to supply materials of short half-life because they cannot be stockpiled for an appreciable length of time. They must be produced currently to meet current and fluctuating demands. Of the total number of radioisotope shipments made thus far over 65 per cent have been shipments of phosphorus 32 or iodine 131, having respective half-lives of 14.3 days and 8.0 days.

FIG. 3. NUCLEAR REACTOR—URANIUM PILE

The functional parts of the nuclear reactor are the fissionable material (uranium), the moderator material (graphite) and the control rods (boron steel). The uranium slugs are inserted into the pile from the right face (where the elevator is located). They are discharged at the opposite side of the pile into a channel located between the graphite and concrete. The slugs drop into water and are later chemically treated for removal of the fission products. The radioisotopes formed by the neutron bombardment of stable isotopes are irradiated in graphite holders or stringers as indicated on the left. The control rods are lowered into the pile to retard or stop the chain reaction. The thick concrete wall surrounding the reactive portion of the pile serves as protection for operating personnel.

Most of these shipments have been for medical and clinical investigations.

Today, pile production of radioisotopes has been stepped up to a point where these valuable research tools are available to all qualified investigators. In fact, the situation existent before the advent of pile production, when there was not an adequate supply of radioisotopes to meet the demands of qualified investigators, has been reversed. The present limitation to wider use of radiomaterials is the lack of personnel having the special training and facilities to use them safely. And yet, the number of qualified investigators has been multiplied several times above the prewar level.

AVAILABILITY

Radioisotopes are potentially hazardous to health and for this reason special facilities and techniques are required in handling and using them. The Atomic Energy Commission's primary concern in making radioisotopes available is that they will be used safely. To insure this provision, the Commission has set up certain criteria for the allocation of radioactive isotopes. The Commission has also procured the services of an Advisory Committee on Isotope Distribution to assist in the allocation of these valuable and yet potentially hazardous materials.

The Subcommittee on Human Applications, a subcommittee of the main Advisory Committee, reviews all radioisotope requests proposing use of radiomaterials in humans. This subcommittee has outlined the following general aims governing the distribution of radioactive materials for medical purposes: (1) to make radioisotopes available for approved clinical investigations and for diagnostic and therapeutic purposes where they are needed and can be handled properly and safely; (2) to protect, as far as possible, patients from indiscriminate use of radioisotopes; and (3) to insure that adequate facilities are available for those planning to use the material.

In carrying out these very worthwhile aims the Commission is faced with two opposing purposes: first, to make these materials widely available and of maximum usefulness to medical research and second, to limit distribution sufficiently to guarantee their safe utilization. To achieve the desired balance between these two somewhat contradictory purposes, the Subcommittee on Human Applications has formulated criteria for allocation.

Criteria of Allocation

These criteria have proved satisfactory for the administration of the distribution program. Their merit is clearly evident from enumeration of the requirements: (1) physicians using radioactive material must be associated with a medical research institution, hospital, clinic or other organization having adequate facilities for handling the material; (2) such facilities must provide clinical care of the patient and adequate means for assaying, safely handling and disposing of the radioactive material; (3) the organization requesting the radioisotopes must be in good standing with the local medical society; (4) it is also strongly recommended that the requesting institution appoint a clinical "Isotope Committee" to evaluate all proposals for clinical use of the material within the institution; (5) the scientifically trained individual who will use or directly supervise the use of radioactive material must be an accredited physician in good standing with the local medical society; (6) also, the physician must have had previous clinical experience with radiation or radioactive materials or be directly collaborating with an individual possessing such training and experience.

In connection with the above recommendation the Subcommittee on Human Applications has recently adopted the policy of not approving a radioisotope request unless it bears a written statement of approval from the local clinical isotope committee. It is suggested that this local committee includes: (a) a physician trained in internal medicine; (b) a physician trained in hematology; (c) a person experienced in assay of radiomaterials and protection of personnel against ionizing radiations; and, whenever possible, (d) a qualified physicist, and (e) a therapeutic radiologist. If a physicist and radiologist are not staff members of the requesting institution, they should be available in a consulting capacity.

Information indicating that the requesting institution meets these qualifications together with more detailed information concerning the proposed use of the material and proposed health safety measures is forwarded by the applicant in his formal request. Following review and approval of the request by the Subcommittee on Human Applications, the applicant is authorized to procure the material. Subsequent arrangements concerning purchasing the material and scheduling of shipment are made between the applicant and the supplier.

If the radioactive material is not intended for use in humans, the request is not reviewed by the Subcommittee on Human Applications. For animal studies, as well as for all other types of radioisotope investigations, prior reference of all requests to a local isotope committee is strongly recommended. In institutions where clinical and non-clinical investigations are carried on by different groups, a separate isotope committee may be established for the control and coordination of the use of isotopes in the non-clinical studies. Review by a local committee assures the Commission that the proposed program is considered to be both feasible and safe from the standpoint of the institution.

Basic and Special Products

When the Atomic Energy Commission inaugurated its distribution program, it focussed its attention primarily on producing a wide variety of isotopes rather than on producing a wide variety of compounds of a small number of isotopes. Indeed, early production was aimed at making

the largest number of isotopes available in the simplest and most generally adaptable forms. By thus placing emphasis on producing simple basic forms for each isotope it has been possible to make these "basic products" available cheaply and on a large scale.

In many instances, the radioisotope users can conveniently use the materials in the simple basic forms as shipped. Radioiodine (I 131) and radio-phosphorus (P 32), for instance, are often clinically administered as solutions of sodium iodine and disodium hydrogen phosphate which are the chemical forms in which the materials are shipped from the production site. In other cases, however, users may require a modified form or even a specially synthesized compound containing the isotope.

These specially synthesized compounds containing radioisotopes, "labeled" compounds, are extremely important to clinical and medical investigations because they permit tracer studies to be made of the molecules and parts of molecules which enter into biochemical and physiological processes. The element carbon, for instance, is one of the body's major constituents, although, of course, not in its elemental form. Indeed, it is always found in some complex molecule such as an amino acid or sugar. Therefore, in using radioactive carbon 14 to study a certain body compound it is necessary first to incorporate the radioisotope in the specific compound to be studied. These labeled or tagged compounds can be classed as "special products." They may vary from simply the modification of the material shipped, say from the carbonate into sulfate or sulfide, to the complicated synthesis of complex organic molecules.

The Commission has not undertaken an extensive program within its own facilities to prepare and make available these special products. It would not only be difficult for the Commission to maintain facilities and personnel to meet all the special needs of off-Commission users, but this is an area of endeavor which is free of security considerations and one which logically should be handled by private enterprise. Limited quantities of labeled compounds which are obtained as by-products of Commission research activities are made available to off-Commission laboratories when prepared in excess of Commission needs.

The Commission has, however, encouraged commercial firms to engage in the preparation of special products. At the present time three organizations outside Commission laboratories are preparing and distributing isotope-labeled compounds and several other organizations are considering arrangements for initiating similar programs. There are over 50 such compounds now available and 35 additional compounds are scheduled to become available within the next six months. Although most of these compounds are labeled with radiocarbon (C 14), some compounds have been labeled with radioisotopes of sulfur, iodine, gold, zinc and cobalt.

Even though allocation of these materials is necessarily controlled by the Commission, all other arrangements relative to their procurement are made by the supplier and the radioisotope user. Also in its effort to encourage preparation and sale of isotope-labeled compounds by private enterprise, the Commission has adopted the policy of discontinuing distribution of any compound which becomes available from an outside source.

Besides its efforts to encourage wider use of radioisotopes through cooperating with private enterprise in programs such as mentioned above and through its support of training and educational programs, the Commission has also stepped up and amplified its own program of producing basic radioisotope products. New facilities for producing and processing these products are being designed and constructed. The Commission has made an effort to encourage the growth of medical and biological research and evidence of this was noted last April when it was announced that radioactive phosphorus (P 32), radioactive iodine (I 131), and radioactive sodium (Na 24) would be made available free of production costs for use in therapy, diagnosis, and research in cancer and allied diseases. More recently a further announcement was made stating that this program would not only be continued but expanded to include all isotopes normally available under its isotope distribution program providing the material is used in cancer research. More specifically the supplementary extension of the program provides for allocation of materials free of production cost for use in (1) cancer investigations involving animal

subjects, (2) research programs studying basic cellular metabolism of cancerous cells, and (3) experimental programs designed to evaluate the uses of radioactive materials in the therapy and diagnosis of cancer.

CONCLUSION

In pointing out the present widespread availability of radioisotopes as a research tool, it must also be noted that this is based on much more than merely the increased availability of isotopes per se. Not only are radioisotopes available in amounts many times the prewar quantities, but they are also readily available as a much greater variety of radioelements. Nearly all the biologically useful radioisotopes, including such important ones as radiohydrogen (tritium, H 3), radiocarbon (C 14), radiophosphorus (P 32), radiosulfur (S 35), radiocalcium (Ca 45), radioiodine (I 131), etc., are produced routinely and are available continuously.

Further, a stock of isotope-labeled compounds is available for the first time. Many complex organic molecules have been labeled or tagged with iso-

topes and many more will become available in the near future. Heretofore, tracer studies with isotopes were usually limited to following only the radioelement or its simple compounds. The availability of a wide variety of labeled organic and biochemical compounds will certainly promote much more extensive and diversified utilization of isotopes in biology and medicine.

Increased availability of materials and instruments has led recently to a much greater number of hospitals, clinics and other institutions using radioactive materials in routine diagnosis and therapy procedures and in research investigations. Before the war, for instance, little more than a dozen institutions were routinely using radio-phosphorus (P 32) and radioiodine (I 131) in diagnosis and therapy. Today 80 different institutions are using either or both of these isotopes in this type of clinical work.

It seems quite certain that with the background at hand and the impetus now gained, future research with isotopes, especially isotope-labeled compounds, will lead to valuable new routine uses of radioisotopes in diagnosis and therapy.

THE USE OF STABLE ISOTOPES IN BIOLOGICAL AND MEDICAL RESEARCH

By IRVING M. LONDON

(From the Department of Medicine, College of Physicians and Surgeons, Columbia University, and The Presbyterian Hospital in the City of New York)

During the past 15 years there has been a rapid and extensive development of the use of isotopes in biological and medical investigation. In 1923, Hevesy's pioneering studies, in which thorium B was used to investigate the absorption and localization of lead by plants, revealed some of the possibilities of the use of tracer technique for biochemical research. The exploitation of these possibilities marked time, however, until isotopes of elements more widely associated with biochemical processes were made available. The discovery of deuterium by Urey in 1931 and the development of methods for production of heavy water were the first steps toward providing stable isotopes for tracer studies in biological systems.

There soon followed the preparation of the heavy isotopes of nitrogen, carbon and oxygen, which, with hydrogen, constitute a large portion of the elements of interest to the biologist. The discovery of artificial radioactivity by Joliot and Curie in 1934 led before long to the production of a number of radioactive isotopes which are of value in biological investigations. The past decade and a half have witnessed a swift and enthusiastic application of stable and radioactive isotopes to a wide variety of biologic studies.

The reports of these studies form a voluminous literature. Several reviews (1-7) which deal with various aspects of tracer research have appeared in recent years. The scope of the present discussion is limited to the use of stable isotopes and it is not the purpose of this paper to attempt another review, which would require far more space than is available. This paper is designed to indicate some of the types of investigative problems for which tracers are particularly suited and to present illustrative examples of studies in which stable isotopes have been used.

The discussion is presented in two parts. *I.* Types of problems for which isotope investigation is suitable. *A.* Problems of dilution and transport—the addition of isotopic substance A to a biologic system and the subsequent isolation of substance A and the determination of its isotope

content. *B.* Problems of conversion—the addition of isotopic substance A to a biologic system and the subsequent isolation of substance B and the determination of its isotope content. *C.* Kinetics of biochemical reactions. *II.* An illustration of the use of isotope techniques in the investigation of related problems in one field: the biosynthesis and metabolism of porphyrins.

Problems of Dilution and Transport

Shortly after Hevesy's first experiments with thorium B, one of his colleagues expressed the hope that a tracer would be found which could permit the determination of the fate of individual water molecules such as those in the tea they were about to drink (8). Within a decade Urey's discovery of deuterium and preparation of heavy water had provided an indicator which could help in the solution of such a problem. This type of problem is characteristic of a number of questions which can be answered by a basically simple application of the isotope technique. This application consists in introducing a labeled substance of known isotope concentration into a system and subsequently measuring the isotope concentration of the same substance in the system as a whole or in one or more of its constituent units. One can trace the fate of the labeled substance, *i.e.*, its distribution and localization, and one can measure the time relationships of its distribution. In terms of biological experimentation, this technique is applicable to the study of mechanisms and rates of transfer of biological substances by absorption, secretion or excretion and to the study of diffusion and membrane permeability. The same technique is applicable to the solution of quantitative analytic problems, whether primarily biological or chemical. By determining the dilution in isotope concentration of the labeled substance after its addition to the system one can determine the amount of this substance which is present in the system. In the animal organism precise measurements of a variety of body constituents are made possible, and in a purely chemical system,

the isotope dilution method affords a precise technique for quantitative analysis.

A few examples which are representative of the various applications of this type of tracer work may serve to illustrate the use of the technique. Hevesy and Hofer investigated the rate at which water is eliminated from the human body (8). They administered heavy water to a subject and subsequently measured the deuterium concentration in the urine. By determining the interval between the time of maximal concentration of deuterium in the urine and the time when the deuterium concentration in the urine was one-half the maximal value, they determined $t_{1/2}$, the time required for one-half of the heavy water ingested to be eliminated from the body. This value is nine days. Inasmuch as the biologic behavior of heavy water of low isotope concentration is essentially the same as that of ordinary water, this value for $t_{1/2}$ applies equally to ordinary light water. The average time which a water molecule spends in the body is $t_{1/2} \times \ln 2$, or 13 days.

In the same study, these investigators applied the principle of isotope dilution to determine the water content of the body. After the first day the deuterium concentration in the water of urine may be taken as the deuterium concentration in total body water. This is based on the reasonable assumption that the heavy water becomes completely mixed with the total body water and is handled in the body in a manner indistinguishable from that of ordinary water. The total body water volume is then equal to the product of the deuterium concentration and the volume of the heavy water administered divided by the deuterium concentration in the urine. These calculations yielded a value for total water volume of 43 ± 3 liters or 63 ± 4 per cent of the body weight. This method was modified by Moore (9) who determined the deuterium concentration in plasma one hour after the intravenous injection of heavy water. Complete equilibration of the injected D_2O with the body water was found to occur within one hour; consequently the deuterium concentration in the one-hour plasma sample could be considered equivalent to the deuterium concentration in total body water. By this method, a value for total body water of 47.8 liters or 72 per cent of the body weight was obtained in a normal adult male.

The ability of the tracer technique to follow the transfer of a substance across a membrane has

permitted the study of a number of biological problems which could not be satisfactorily investigated by other methods. Without the aid of isotopes, the measurement of such transfer would depend on the determination of the net change in the quantity of the substance on each side of the membrane. Under physiological conditions, however, little or no net change in the quantity of a great many substances is found despite considerable transfer, for the transfer takes place simultaneously in both directions across the membrane. The isotope technique avoids this difficulty. By introducing a labeled substance on one side of the membrane one can follow the movement of the labeled substance in a system at equilibrium or in a steady state. Inasmuch as the biochemical behavior of labeled units is indistinguishable from that of unlabeled units of the same substance, the transfer of the labeled substance is representative of the transfer of the substance as a whole.

The studies of Gellhorn and Flexner (10) on the transfer of water across the placenta illustrate this application of the isotope technique. D_2O was injected into a pregnant guinea pig, and after ten minutes during which equilibration of D_2O between the various fluid compartments of the mother was known to occur, the fetuses were delivered by Caesarean section. By determining the total body water of the fetus and the deuterium concentrations in maternal and fetal plasma, it was possible to calculate the quantity of water transferred across the placenta per unit time. It was found that the rate of transfer of water across a unit weight of placenta from the 28th day of gestation to term increased about nine times, and that the rate of transfer of water to a unit weight of fetus was parallel to the relative growth rate of the fetus.

The principle of isotope dilution has found ready application to quantitative analytic studies (11-13). Most commonly, a small known amount of labeled substance is added to a system containing an unknown amount of the same substance unlabeled. By determining the dilution in the isotope concentration of the substance isolated from the system, the quantity of substance originally present in the system can be calculated. This technique permits accurate quantitative determinations of a large number of substances for which other good quantitative methods may not be available. In addition, the need for quantitative isola-

tion of the substance is obviated. A pure sample adequate in amount for isotope analysis is sufficient. For accurate results it is essential that the labeled material which is added to the system and the material isolated from the system be pure.

The isotope dilution method has been used to determine quantitatively the optical isomers of amino acids present in amino acid mixtures (14) and to determine the amino acid content of horse hemoglobin (15) and human and bovine albumin (16). Its use has demonstrated that the claim for the presence of large quantities of D-glutamic acid in malignant tumor tissue is invalid (17).

A modification of this procedure has been described by Keston, Udenfriend, and Caman (18) for amino acid analyses. A mixture of amino acids is treated with a labeled substance, *e.g.*, p-iodophenylsulfonyl chloride labeled with I^{131} . A large amount of the non-isotopic p-iodophenylsulfonyl derivative of the amino acid to be measured is added to the mixture and the compound is subsequently isolated and its specific activity (isotope concentration in the case of stable isotopes) determined. Inasmuch as stable derivatives may be formed with other amino acids in the mixture, the isolated compound may require numerous recrystallizations before purity is established. It should be noted that complete conversion of the amino acid to its derivative must occur if accurate results are to be obtained. This method permits the quantitative determination of microgram quantities of amino acids.

The principle of isotope dilution has been applied in reverse by Bloch and Anker (19) to determine the isotope concentration of a metabolite present in too small an amount to permit direct isolation. Since the amount of isotopic metabolite is also unknown, the addition of a known amount of nonisotopic metabolite (carrier) merely facilitates isolation, but calculation of the original isotope concentration of the metabolite is not possible. If two different quantities of normal carrier are added to separate aliquots of the metabolite solution, however, the two samples of metabolite subsequently isolated will have different isotope concentrations. Sufficient data are then available for calculation of the original isotope concentration. The error of this procedure, however, may be as high as 20 per cent.

Problems of Conversion

Isotopes are particularly suited to the study of conversion reactions. One of the principal types of investigation in intermediary metabolism is concerned with determining the products of the biological conversion of a substance or to determine its biologic precursors. Experiments performed without the aid of isotopes are for the most part of two types: (1) *in vivo* studies in which substance A is administered and the quantity of substance B which is formed in the tissues or is excreted is determined; and (2) *in vitro* studies in which substance A is added to tissue slices or isolated organs and the quantity of substance B formed in the system is measured. Although these types of study have yielded much valuable information, they do not yield conclusive evidence for the determination of biologic precursors or conversion products. *In vivo* studies in which an increased excretion of substance B following the administration of substance A is interpreted as evidence that A is a biologic precursor of B, are open to the criticism that increased excretion of B represents an increased loss of B from the organism rather than increased synthesis and that A is responsible for this effect merely by virtue of its effect on the excretory mechanism. An increased formation of B *in vivo* or *in vitro* following the addition of A does not prove the conversion of A to B but may indicate rather that A is concerned in reactions yielding energy required for the synthesis of B. Furthermore, the absence of increased formation of B following the administration of A does not preclude the role of A as a specific precursor for B. Most biologic syntheses involve a series of reactions. Only one of these reactions may be limiting and principally responsible for the rate of formation of B. If the specific conversion of precursor A to substance B is not this limiting reaction, the administration of A will probably not be reflected by an increased formation of B. Clearly another technique of investigation which offers unequivocal evidence for the specific utilization of structural components of one substance for the biologic synthesis of another is required. Such is the isotope technique.

A striking example of the use of isotopes in the study of conversion reactions is the investigation of the biological synthesis of creatine and creatinine. Bloch and Schoenheimer (20) addressed their attention first to the relationship *in vivo* of

creatine to its anhydride, creatinine. Creatine labeled with N^{15} was fed to rats and subsequently creatine was isolated from the muscles and creatinine from the urine. The N^{15} concentrations in the isolated creatine and creatinine were nearly identical and indicated that urinary creatinine is derived from body creatine. Similar studies were carried out in which after the preliminary period of feeding N^{15} labeled creatine, the rats were kept on a creatine-free diet, during which time the isotope content of urinary creatinine was identical with that of body creatine. This finding indicated that body creatine is the sole precursor of urinary creatinine in an animal on a creatine-free diet. Were any other nitrogenous source present, the isotope concentration in the creatinine would have been lower than that of the body creatine as a result of dilution with non-isotopic nitrogen.

To determine whether the creatine \rightleftharpoons creatinine reaction is reversible *in vivo* as it is *in vitro*, isotopic creatinine was administered to rats and body creatine was subsequently isolated. There was essentially no isotopic nitrogen in the creatine, a finding which indicates that *in vivo* creatinine is not convertible to creatine.

The next step in these studies was the search for the biologic precursors of creatine. Clues to the identity of these precursors were provided by Brand *et al.* (21, 22) who found that patients with muscular dystrophy excrete more creatine after administration of glycine, and by Fisher and Wilhelmi (23) who reported that the addition of arginine to the fluid perfusing rabbit hearts resulted in a quantitative conversion to creatine. In addition Borsook and Dubnoff showed that guanidoacetic acid is methylated to creatine in surviving liver slices and that this methylation is markedly accelerated by the addition of methionine; they concluded that the methyl group of methionine is transferred to guanidoacetic acid to form creatine (24). Simultaneous and independent investigations by Bloch and Schoenheimer revealed that when glycine labeled with

N^{15} was administered to normal rats, creatine with a high isotope content was formed (25). Similarly sarcosine labeled with N^{15} yielded creatine with equally high isotope content. Inasmuch as the ingestion of isotopic sarcosine was shown to lead to the deposition in proteins of isotopic glycine to the same extent as when glycine itself was fed, it was concluded that sarcosine is very rapidly demethylated after its ingestion and that it serves as a precursor of creatine only after demethylation to glycine (26). When guanidoacetic acid labeled with N^{15} was fed, creatine was formed with an isotope content approximately the same as when an equivalent amount of isotopic creatine was administered; clearly, methylation of guanidoacetic acid to form creatine must occur quickly (25).

With the role of glycine as a precursor established and with the demonstration of the rapid methylation of guanidoacetic acid to form creatine, there yet remained the problem of determining conclusively the biologic sources of the various groups in the creatine molecule. Working independently, Borsook and Dubnoff found that kidney slices could form guanidoacetic acid from arginine and glycine (27) and Bloch and Schoenheimer showed that the administration of arginine labeled with N^{15} in the amidine group resulted in the formation of creatine of high isotope concentration (28). By degradation studies the latter investigators were able to show that the amidine nitrogen of creatine is derived from the amidine nitrogen of arginine, and that the nitrogen of the sarcosine group originates from glycine (29).

The final link was provided when du Vigneaud *et al.* found that the administration to rats of methionine labeled with deuterium in the methyl group results in the formation of creatine with a high deuterium concentration (30, 31).

These studies established the immediate biological source of each part of the creatine molecule. The biosynthesis of creatine may be summarized as follows:

Recent studies on the biosynthesis of uric acid offer another example of the use of the isotope technique in establishing the identity of the biologic precursors of an important chemical substance. Sonne, Buchanan and Delluva (32-34) prepared a number of compounds labeled with C^{13} , administered them to pigeons, isolated the uric acid from the excreta, and degraded the uric acid by procedures which permitted separate isotope analyses of each of the carbon atoms in the uric acid molecule. They found that the number 6 carbon is derived from CO_2 , carbon atoms 2 and 8 from the carboxyl carbon of acetate (CH_3C^*OOH) or formate (HC^*OOH), and carbon atom 4 from the carboxyl carbon of glycine ($CH_2NH_2C^*OOH$). Shemin and Rittenberg (35) demonstrated the specific utilization of the amino group of glycine for nitrogen 7 in an experiment in which N^{15} labeled glycine was fed to a human and the uric acid isolated from his urine was degraded. Nitrogen atoms 1, 3 and 9 are apparently derived from ammonia of the general metabolic pool. With glycine established in positions 4 and 7, it remained for Karlsson and Barker (36) using glycine labeled with C^{14} in the α position to show that the methylene carbon of glycine is incorporated into position 5 ($NH_2C^*H_2COOH$). These composite data derived from both avian and human experiments have established the immediate biologic precursors of each component of the uric acid molecule.

Progress in the delineation of the conversion reactions in intermediary metabolism has been markedly facilitated by the use of isotopes. Limitations of space prevent discussion of the many excellent studies which illustrate this application of tracer technique. The interested reader is referred to reviews or representative papers by Wood (37), Evans (38), Gurin (39), Stetten (40), Weinhouse (41) and their colleagues for a more thorough consideration of the use of tracers in the study of conversion reactions.

Kinetics of Biochemical Reactions

Within a few years after the start of their investigations in intermediary metabolism with the aid of isotopes, Schoenheimer, Rittenberg and their colleagues concluded that the conventional concept of the division of metabolic processes into exogenous and endogenous forms was untenable.

Their studies demonstrated that there is a constant interchange of dietary constituents with body constituents and that the body constituents are in a state of flux, of continuous synthesis, degradation, and interchange. They termed this concept of intermediary metabolism "the dynamic state of body constituents." This concept not only comprises an appreciation of the interconversions and synthetic and degradative reactions of body constituents, but it emphasizes the importance of the rates at which these reactions are carried out in the living organism. The kinetics of processes in intermediary metabolism has received relatively little attention, however, as compared with the attention focussed on delineating the pathways of synthesis and degradation. In the future, however, the kinetic aspects of biologic processes may be expected to receive considerably more emphasis in isotope studies. An appreciation of the importance of a metabolic road requires a knowledge of the extent of the traffic on that road. When more than one pathway for the conversion of one substance to another exists, the rates at which the reaction is carried out via the different routes indicate the relative significance of these routes.

Studies in reaction kinetics are pertinent to the investigation of chemical changes in biological fluids and tissues which occur in disease. By determining reaction rates, it is possible to ascertain whether an abnormally high concentration of a substance is the result of an increased rate of synthesis or a diminished rate of degradation, and whether an abnormally low concentration results from a diminished rate of synthesis or an increased rate of degradation.

The considerations and calculations involved in the measurement of reaction rates in isotope experiments have been discussed by Zilversmit *et al.* (42), by Branson (43), and by Radin (44). The principal consideration is the basic assumption of biological isotope research, namely, that isotopic molecules are biologically indistinguishable from non-isotopic molecules. In nearly all cases the additional assumption may be made that the appearance and disappearance of all molecules proceed at random. The simplest type of problem of reaction kinetics is concerned with a biological system in the steady state, *i.e.*, the rate of appearance of the substance under study equals its rate of disappearance and, during the period of study, these rates remain constant. Under these conditions, the total number of molecules, M , of the substance in the system is equal to m , the number of molecules which enter (or leave) the system per unit

of time, multiplied by the turnover time, \bar{T} , the time required for the appearance in the system or disappearance from the system of M molecules of the substance.

One type of experiment in which the rate of synthesis and degradation of a substance may be calculated is that in which a small amount of the labeled substance which is normally synthesized in the system is added to the system and its rate of disappearance is measured. In the steady state the rate of disappearance is equal to the rate of appearance and is consequently a measure of the rate of turnover. The rate of creatine turnover was studied by this technique (45). Adult rats were given isotopic creatine and were then placed on a creatine-free diet. Samples of creatinine were isolated at intervals from the urine. The isotope content of the creatinine was shown in the studies described earlier to be the same as that of the body creatine. The decrease in isotope concentration in the urinary creatinine indicates therefore the disappearance of labeled creatine from the tissues and its replacement by newly synthesized non-isotopic creatine. The curve of isotope concentration in the creatinine declines in exponential fashion, *i.e.*, the decline in isotope concentration at any moment is proportional to the isotope concentration at that moment. Since the slope, K , of the declining isotope concentration curve is equal to $\frac{m}{M}$, *i.e.*, the fraction of the total substance M which disappears from the system per unit time, and since i is the isotope concentration at any time t , then $\frac{di}{dt} = -ki$.

On integration $i = i_0 e^{-kt}$, in which i_0 is the isotope concentration at the start of the experiment. On converting to logarithmic values, $\ln i = \ln i_0 - kt$. A plot of $\ln i$ against t yields a straight line whose slope is k . Accordingly, by serial determinations of the isotope concentration, k can be calculated, and $t_{1/2}$, the half life-time, can be determined from the equation $t_{1/2} = \frac{\ln 2}{k}$. Since $\bar{T} = t_{1/2} \times \ln 2$, the turnover time is also readily calculated. To express the rate of turnover in terms of units of weight per unit of time, M must be determined quantitatively by an independent procedure.

In the case of creatine in rats, the turnover rate was found to be about 0.02 per day. By determining the total body creatine, and the daily urinary creatinine excretion, it was found that the daily creatinine excretion corresponds to about 2 per cent of the total body creatine. The close agreement of these values for daily synthesis of creatine and excretion of creatinine precludes the existence of any major catabolic pathway for creatine other than creatinine formation and excretion.

Hoberman *et al.* (46, 47) have utilized this technique to study the rate of turnover of body creatine in man. In two human male subjects on a creatine-free diet values of 42 and 48 days for the half lifetime of body creatine were obtained $\left(t_{1/2} = \frac{\ln 2}{k} = \frac{0.69}{0.0164} = 42; \frac{0.69}{0.0143} = 48 \right)$. When methyl testosterone is administered to the normal subject, the slope of the curve becomes steeper and reflects a more rapid dilution of body creatine (47). By

appropriate calculations it can be shown that the more rapid dilution is the result of an increased rate of synthesis of creatine and an increase in the total body creatine. This study affords direct evidence that methyltestosterone accelerates creatine synthesis.

When it is very difficult to synthesize an isotopic compound whose biologic turnover is to be studied, it may be possible to prepare the compound by biosynthesis and to study its turnover in the same or in another organism. An isotopic compound which is known to be a biologic precursor of the substance is administered to the subject and subsequently the substance is isolated serially and its isotope concentration is determined. In the case of substances in the dynamic state, the isotope concentration rises to a maximum shortly after the end of the administration of the isotopic precursor and then declines exponentially. The upward slope of the curve reflects the appearance of newly synthesized labeled molecules and their replacement of unlabeled molecules formed prior to the administration of the isotopic precursor. The declining portion of the curve results from the disappearance of labeled molecules and their replacement by newly synthesized molecules containing little or no isotope. Inasmuch as the degradation of the labeled molecules may in some cases result in isotopic fragments which can be reutilized for the synthesis of new molecules of the same substance, the rate of decline in isotope concentration may be slower than the actual rate of degradation. This discrepancy is probably not marked, however, for after the degradation of the labeled molecule, the isotopic fragment commonly enters a metabolic pool of similar fragments of lower isotope concentration. A representative sample of this pool is utilized for the synthesis of new molecules. These conditions approximate roughly the replacement of isotopic molecules by non-isotopic molecules and provide a good measure of the turnover rate of a substance in the dynamic state. This technique has been used to study the rates of turnover of serum and antibody proteins in the rabbit in whom it was found that the half lifetime of serum and antibody protein molecules is about two weeks (48). Shemin and Rittenberg have utilized this technique in an extensive study of the interrelationships involved in nitrogen transfer and of the rates of turnover of nitrogen in various tissues of the rat (49).

FIG. 1. N^{15} CONCENTRATION IN SERUM PROTEINS AFTER FEEDING N^{15} LABELED GLYCINE FOR TWO DAYS

The kinetics of serum protein formation in the human have been investigated by this method (50). Glycine labeled with N^{15} was fed to a human subject for two days and the N^{15} concentrations in the total protein were determined. Figure 1 shows a curve representative of the data obtained in these studies. The maximal N^{15} concentration is reached shortly after the cessation of feeding labeled glycine and thereafter the isotope concentration declines in a roughly exponential manner. The $t_{1/2}$ value for total serum protein is about ten days.

With a $t_{1/2}$ of about ten days, the turnover time, \bar{T} , for a serum protein molecule is $t_{1/2} \times \ln 2$ or about 15 days. The normal human adult male with a total plasma volume of 45 ml. per kilogram of body weight has a serum protein content of about 3 Gms. per kilogram of body weight. Substitution in the equation $M = m \times \bar{T}$ yields a value for m of 0.2 Gm. of serum protein per kilogram of body weight per day. In a normal man of 70 kilograms, approximately 14 Gms. of serum protein are synthesized and degraded daily. It should be remembered that $t_{1/2}$ values are approximations and are somewhat greater than the actual half lifetimes. Accordingly, the shorter actual half lifetimes will be reflected in proportionately greater rates of synthesis and degradation.

A theory and a practical procedure for evaluation of the rate of protein synthesis have recently been described by Sprinson and Rittenberg (51). A small amount of N^{15} labeled amino acid is administered to the subject and the N^{15} content in the urine excreted after the administration of the amino acid is determined. The greater the utilization of the amino acid for protein synthesis, the

smaller the total excretion of N^{15} during the period of study. Mathematical treatment of the data on the cumulative excretion of N^{15} during a period of 48 to 72 hours after ingestion of the isotopic amino acid affords an estimation of the rate of protein synthesis and the size of the metabolic pool of nitrogen. The rate of protein synthesis per kilogram of body weight per day is approximately 0.2 Gm. of nitrogen in adult man. The nitrogen pool, *i.e.*, the nitrogenous compounds which are derived from the diet or from the degradation of body constituents and which are utilized for the synthesis of tissue constituents, was found to be approximately 0.4 – 0.6 Gm. per kilogram in normal man. This procedure should prove to be valuable in the study of a variety of metabolic disorders and in the investigation of endocrine effects on nitrogen metabolism.

The rate of synthesis and degradation of a biologic substance can be determined by still another technique which measures the rate of incorporation of deuterium into the compound from the body fluids. This technique is applicable only to metabolic reactions in which hydrogen, or deuterium, is stably bound to carbon. By maintaining a steady deuterium concentration in the body fluids

FIG. 2. DEUTERIUM CONCENTRATION IN SERUM CHOLESTEROL PLOTTED SEMILOGARITHMICALLY

C_t = deuterium concentration at any time t . C_∞ = maximum deuterium concentration which is attained at infinite time.

and by serial determinations of the deuterium concentration in the substance under study one can measure the rate at which the substance is synthesized. The maximum deuterium concentration which is achieved in this substance is usually lower than that of the body water since a fraction of the hydrogen atoms of most compounds is not derived from body water. The half lifetime of a substance is the time required to reach 50 per cent of this maximum concentration. Studies on the rate of formation of body cholesterol in the mouse have shown a half lifetime for the cholesterol molecule of 15 to 25 days (52). The rate of synthesis of serum cholesterol in a normal man has recently been investigated by this technique. Figure 2 describes a curve obtained by plotting the isotope concentration against time

$$\left[\log \left(1 - \frac{\text{deuterium concentration at time } t}{\text{maximum deuterium concentration}} \right) \text{ vs. time} \right].$$

The linear curve indicates that the change in isotope concentration is exponential in character and from the slope of the curve the half lifetime of serum cholesterol can be determined. In this normal male subject, the half lifetime is about nine days, the turnover time about 13 days (53).

The Biosynthesis and Metabolism of Porphyrins

The preceding discussion has been concerned with presenting examples of the main types of biological problems which are readily investigated with the aid of isotopes. These studies are for the most part unrelated and are diffusely spread over a number of fields of research. It may be well, therefore, to present an account of studies which illustrate the application of a variety of isotope methods to the investigation of a group of related problems in one field. The studies to be described are concerned with the biosynthesis and metabolism of porphyrins.

These studies were initiated with the finding by Shemin and Rittenberg that glycine is specifically utilized for the biologic formation of the protoporphyrin of hemoglobin (54). When glycine labeled with N^{15} is fed to a human, the hemin isolated from the red blood cells of the subject is found to contain N^{15} (55). Serial determinations of the N^{15} concentration in the hemin describe a curve (Figure 3) (55, 56) which is strikingly different from the type of curve of isotope con-

FIG. 3. N^{15} CONCENTRATION IN HEMIN AFTER FEEDING N^{15} LABELED GLYCINE FOR TWO DAYS

centration observed in serum proteins after the administration of labeled glycine (Figure 1). The phenomenon observed in the case of serum proteins represents a dynamic process in which protein molecules are continuously being degraded and resynthesized. If hemin were in the dynamic state, even though the red cell itself were morphologically intact, the N^{15} concentration in the hemin would describe a similar curve. The curve of N^{15} concentration in hemin is fundamentally different, however, and cannot be the result of a random synthesis and degradation of hemoglobin in the peripheral blood. The presence of hemoglobin labeled with N^{15} in erythrocytes many weeks after the end of glycine administration must be due to synthesis and incorporation of hemoglobin labeled with N^{15} in the erythrocytes during formation of the cells in the bone marrow. The persistence of labeled hemoglobin in the red blood cells for months after its synthesis in the bone marrow indicates that once incorporated into the red cell the hemoglobin remains with the cell until the cell disintegrates. In brief, the persistence of the labeled hemoglobin reflects the survival or life span of the cells containing the hemoglobin.

The upward slope of the curve of isotope concentration in hemin represents the release into the circulation of erythrocytes containing isotopic hemoglobin and their replacement of cells formed prior to the administration of glycine which contain no isotopic hemoglobin. The maximum iso-

tope concentration is reached and maintained when cells with heme of insignificant N^{15} concentration replace cells formed before the glycine administration. The declining portion of the curve reflects the destruction of cells containing labeled hemoglobin and the point of inflection represents the period of most marked destruction of these cells. The moderately abrupt decline indicates that the heme is not significantly, if at all, reutilized for new hemoglobin formation when the cell disintegrates. If the heme were reutilized significantly, a slower decline in isotope concentration would occur.

It is clear that normal human red blood cells are destroyed as a function of their age and not in indiscriminate fashion. The average life span of the human erythrocyte can be calculated from the curve of isotope concentration in hemin. These calculations are presented in detail elsewhere (55, 56). Values of 127, 120 and 109 days have been obtained in two normal men and one normal woman. Since these subjects were in a steady state, these values correspond to the production

and destruction of approximately 0.8 per cent of the red cells per day. Despite a rather wide range in the ages at death of the red cell population, the time span which encompasses the ages at death of half (the second and third quarters) of the cell population is relatively short. In the two normal male subjects this time span was found to be 28 and 35 days, in the normal female subject 32 days.

This isotope method possesses the unique advantage of making possible the study of the life span and pattern of destruction of the red cells in the same individual in whom the cells are made and destroyed without altering the usual state of the individual. Accordingly, it is well suited to the study of hemoglobin synthesis and red blood cell dynamics in normal and pathologic states.

Polycythemia vera is one of the clinical disorders which has been investigated with the aid of this method (56). The study was performed in an attempt to determine the factors which might be operative in the production of the characteristic abnormality of the disease, namely, the marked increase in the total number of circulating erythrocytes. Theoretically this increase might result from one or both of these factors: (1) an increased rate of hemoglobin and erythrocyte synthesis and (2) prolonged life of the erythrocytes. A patient in a fully developed stage of the disease was given glycine labeled with N^{15} in a dosage equivalent to that used in the normal subjects. Figure 4 describes the curve of the isotope concentration in hemin. The pattern of red cell destruction is normal and the average life span of the red cells is 131 days, a value close to the values obtained in the normal subjects. Inasmuch as the erythrocyte life span is essentially normal, the marked increase in the number of circulating red cells must be associated with an elevated rate of red cell and hemoglobin synthesis. In this patient the rate of synthesis was 2.5 times the normal value.

These findings demonstrate a functional hyperactivity of the blood-forming apparatus in polycythemia vera in a fully developed stage of the disease. It is likely that the development of the polycythemia earlier in the disease is also characterized by increased hematopoietic activity with the maintenance of a normal erythrocyte life span. Various theories have been proposed for the etiology of polycythemia vera but conclusive

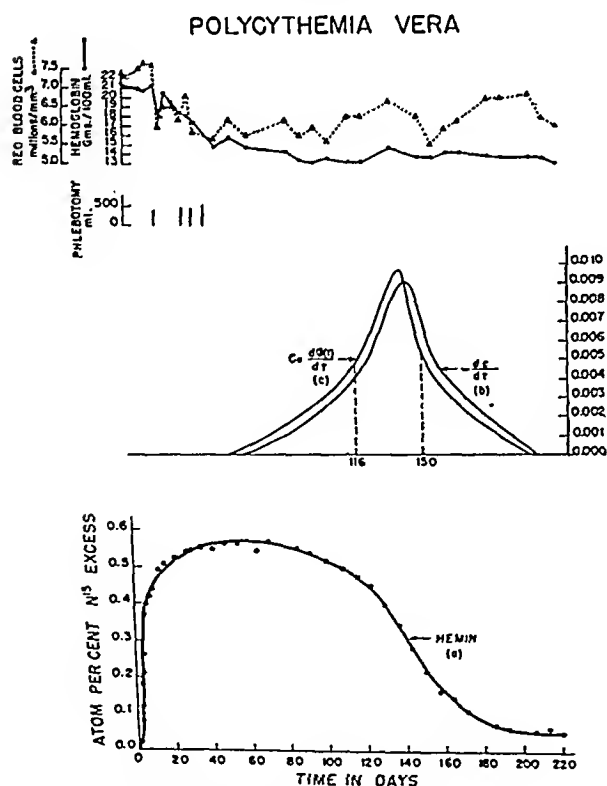

FIG. 4. N^{15} CONCENTRATION IN HEMIN AFTER FEEDING N^{15} LABELED GLYCINE FOR TWO DAYS

proof in support of any of them is lacking. The fundamental cause of the functional hyperactivity of hematopoietic tissue remains unknown. The theory, first proposed by Minot and Buckman (57), that polycythemia vera is a neoplasm, appears to be most compatible with available evidence. The persistent bone marrow hyperplasia involving all marrow elements, the development of leukemia in some cases of polycythemia vera and the development of polycythemia in some cases of leukemia suggest that this is a neoplastic process. It appears to be a benign neoplasm which can develop malignant characteristics. If it is a neoplasm, it is an instance of neoplastic growth which is associated with an increase in synthetic activity with no apparent diminution in degradative activity. The fundamental cause, however, remains no less obscure than that of other forms of neoplasia.

Sickle cell anemia is another clinical disorder which has been investigated with the aid of the isotope method (56). A patient with the characteristic findings of this disease received labeled glycine in a dosage similar to that used in the normal subjects. The curve of isotope concentration in the hemin is shown in Figure 5. It is markedly different from the normal. Following a rapid rise to a maximum on the seventh day, the curve declines exponentially. The exponential decline results from a random disappearance of labeled heme from the circulating blood, *i.e.*, the heme is removed from the circulation at a rate which is independent of the age of the heme at the time of its degradation. A curve of this shape could result from (1) a random destruction of the

red blood cells and a consequent loss of labeled heme from the circulating blood; or (2) a random degradation and synthesis of heme in circulating red blood cells which are morphologically intact; or (3) random synthesis and degradation of heme in red blood cells which are themselves undergoing random destruction. The latter two possibilities seemed unlikely in the light of earlier studies which demonstrated that the hemoglobin of circulating erythrocytes is not in the dynamic state. However, when the whole blood of patients with sickle cell anemia is incubated with N^{15} labeled glycine heme labeled with N^{15} is formed (58). This *in vitro* synthesis of heme indicates that the peripheral blood in patients with sickle cell anemia may synthesize heme. The synthesis in the *in vitro* experiments occurs at a rate of only 0.1–0.2 per cent of the red cell heme in 24 hours. If all the hemoglobin in the circulating erythrocytes of sickle cell anemia were synthesized in the peripheral blood at a rate of the same order of magnitude as in the *in vitro* experiments, the hemoglobin turnover would be ten to 25 times slower than that which is actually observed in this case. It would seem that the random disappearance of heme must be due for the most part to an indiscriminate destruction of erythrocytes. If some random synthesis of heme in the peripheral blood of patients with sickle cell anemia does occur, it probably plays a very minor role in the hemoglobin turnover in this disease.

Inasmuch as the erythrocytes of sickle cell anemia are destroyed indiscriminately, they do not have a true life span and their survival is more appropriately measured in terms of their half lifetime. The half lifetime ($t_{1/2}$), *i.e.*, the time required for the isotope concentration to decline from any given value on the declining portion of the curve to one-half that value, is 29 days in this case. The mean survival time, or turnover time ($t_{1/2} \times \ln 2$), is 42 days. With these data and determinations of total circulating hemoglobin and red blood cell volumes, the rates of hemoglobin and red cell production may be calculated. The rates in this patient were found to be nearly three times the normal.

The increased hematopoietic activity is most likely a compensatory response to the markedly reduced number of erythrocytes. The diminished survival time reflects a defect which is in all prob-

FIG. 5. N^{15} CONCENTRATION IN HEMIN AFTER FEEDING N^{15} LABELED GLYCINE FOR TWO DAYS

ability intrinsic to the red cell. This defect, which probably involves the structure of the red cell membrane, may be associated with the sickling process but cannot be ascribed to this phenomenon alone, since the red cells of individuals with sickle cell trait but without anemia are not abnormally susceptible to destruction (59, 60).

Pernicious anemia is another disease process which has been investigated (56). A patient with the typical physical and laboratory findings of the disease received N^{15} labeled glycine. No anti-anemia therapy had been given when the experiment was begun. The curve of isotope concentration in hemin, the red blood cell counts, hemoglobin values, and reticulocyte counts during the course of the study are shown in Figure 6. The isotope concentration in hemin rose rapidly and was approaching its maximum on the 16th day. It was considered inadvisable to withhold treatment longer and liver extract therapy in large

dosage was begun. A satisfactory reticulocyte response and rise in hemoglobin and red blood cell counts occurred.

The rise in hemoglobin and erythrocyte levels was accompanied by a decline in the isotope concentration in the hemin. This decline was anticipated for a dilution of the isotope concentration in the hemin of circulating erythrocytes should result from the release into the circulation of large numbers of new cells formed when the isotope concentration in the body glycine had fallen to a low value. The decline in isotope concentration persisted, however, after the erythrocyte and hemoglobin values approached normal levels and a mere dilution effect should have been minimal. To differentiate a dilution effect from actual destruction of the cells containing labeled hemoglobin, the changes in the total amount of N^{15} in the heme of circulating erythrocytes were determined. It has been shown (61) that the hemo-

FIG. 6. N^{15} CONCENTRATION IN HEMIN AFTER FEEDING N^{15} LABELED GLYCINE FOR TWO DAYS TO A SUBJECT WITH PERNICIOUS ANEMIA

FIG. 7. TOTAL HEME N¹⁵ AFTER FEEDING N¹⁵ LABELED GLYCINE FOR TWO DAYS

globin concentration in the peripheral blood serves as a reliable index of the total hemoglobin in circulation before and after the start of liver treatment in pernicious anemia. Accordingly, a curve representing the changes in the total amount of heme N¹⁵ in circulation could be obtained by multiplying the hemoglobin concentration in the peripheral blood by the isotope concentration in the hemin (Figure 7).

The initial rise in total heme N¹⁵ is similar to the rise in isotope concentration noted in Figure 6. After the start of liver therapy, an additional rise occurs due to the influx of many new cells. Although these newly formed cells contain heme of relatively low isotope concentration, their total number represents a considerable increment in the quantity of heme N¹⁵ in the circulating blood. The maximum value for total heme N¹⁵ is attained about two weeks after the start of liver therapy. If the cells of untreated pernicious anemia enjoyed a normal life span, the curve would have maintained a plateau until the 40th to 60th day and then would have begun to decline. The curve declines, however, in linear fashion almost immediately after reaching its peak. If all the cells were destroyed indiscriminately, the decline would have been exponential. The linear decline suggests that the cell population is mixed, many of the cells being destroyed indiscriminately and others as a function of their age. From the declining portion of the curve it is possible to calculate that the mean survival time of the mixed cell population is 90 days and that the mean survival time of the cells formed prior to liver therapy is approximately 85 days. These calculations are presented in detail elsewhere (56).

With these data and determinations of total hemoglobin and red blood cell values, it can be shown that the rate of production of erythrocytes capable of reaching the peripheral blood is only about 50 per cent of normal. This diminished rate of production and the diminished survival time of the cells in circulation are consistent with the view that in untreated pernicious anemia the erythrocytes are intrinsically defective. The absence of an abnormal hemolytic factor in the plasma of pernicious anemia patients is supported by studies with the Ashby technique (62, 63) which have shown an essentially normal survival of normal cells transfused to recipients with pernicious anemia. There is no marked deficiency in the rate of production of circulating hemoglobin which in this case was 80 per cent of normal.

After treatment with liver extract for one year, the patient was again studied. The findings reveal that the red blood cells are destroyed as a function of age, not indiscriminately, and that their average life span is 129 days, a normal value. Complete restoration to normal red cell dynamics has occurred (Figure 8).

In the untreated state, this patient showed only mild diminution in the rate of production of circulating hemoglobin. But even a normal rate of production and destruction of circulating red cell hemoglobin fails to provide an adequate explanation for the very large amounts of bile pigment which are produced in pernicious anemia. To investigate this and other problems of bile pigment metabolism, the biologic origin of bile pigment has been studied with the isotope technique.

It has commonly been assumed that bile pigment normally is derived almost exclusively, if not com-

pletely, from the degradation of hemoglobin of mature circulating red blood cells. In accordance with this assumption, the appearance of N^{15} in the bile pigment following the administration of N^{15} labeled glycine should reflect the destruction of red blood cells containing labeled hemoglobin. Since in the normal human no significant number of red cells is destroyed for several weeks after their release into the circulation, there should be no significant concentration of N^{15} in bile pigment during the early part of the experiments in the normal subjects. Stercobilin isolated from the stools collected during the first eight days of the experiment in one of the normal subjects was found, however, to have a high concentration of N^{15} (64). This finding suggests that a portion of bile pigment is derived from one or more of the following sources: (1) hemoglobin of red blood cells which are destroyed shortly after reaching the peripheral blood or never reach it and are destroyed in the bone marrow; (2) porphyrins which are not utilized for hemoglobin production; or (3) direct synthesis of bile pigment via a pathway which does not involve degradation of a porphyrin ring. From quantitative considerations it appears unlikely that myoglobin or the respiratory heme pigments serve as a significant source of this portion of bile pigment.

The finding of an additional source of bile pigment formation appeared to offer a reasonable explanation for the discrepancy in untreated pernicious anemia between the very high levels of bile

pigment production and the relatively moderate destruction of circulating red cell hemoglobin. When a similar study was performed in the patient with pernicious anemia, an extraordinarily high concentration of N^{15} was found in the stercobilin isolated during the first several days of the experiment (65). These findings indicate that a very large portion of the bile pigment produced in this disease is derived from one or more of the additional sources which have been suggested.

The investigation of porphyrin metabolism was facilitated by the finding that heme synthesis occurs *in vitro* in the blood of patients with sickle cell anemia (58) and in avian nucleated erythrocytes (66). Since significant heme synthesis is not observed in normal human blood under similar experimental conditions, the *in vitro* synthesis observed in the blood of sickle cell anemia was believed to be due to the presence of numerous immature reticulated cells. On incubation of blood samples from other subjects with hematologic disorders characterized by elevated reticulocyte counts, however, significant heme synthesis was not observed (58). These findings indicated that although the reticulocytes in the blood of sickle cell anemia might be responsible for the heme synthesis, the mere presence of numerous reticulocytes in the blood of subjects with other hematologic disorders does not insure the ability of such blood to synthesize heme *in vitro*. Further studies (67) have confirmed the finding that some blood samples with elevated reticulocyte counts from patients with other blood dyscrasias do not perform significant *in vitro* heme synthesis. These studies have shown, however, that other blood samples with elevated reticulocyte counts from subjects with disorders other than sickle cell anemia may synthesize heme *in vitro*. To investigate some of the problems posed by these observations, the capacity for heme synthesis of reticulocytes in the blood of experimental animals which had no disorder of erythrocyte or hemoglobin formation was studied. The blood of previously normal rabbits in whom reticulocytosis was induced by bleeding or phenylhydrazine hemolysis was incubated aerobically with N^{15} labeled glycine for 24 hours. The N^{15} concentrations in the hemin of these blood samples revealed that approximately 0.3–0.9 per cent of the total heme in the *in vitro* system was

FIG. 8. N^{15} CONCENTRATION IN HEMIN AFTER FEEDING N^{15} LABELED GLYCINE FOR TWO DAYS

newly synthesized during the 24 hour incubation period. These findings demonstrate that mammalian reticulocytes possess a significant capacity for heme synthesis and suggest that some heme synthesis may occur *in vivo* in the reticulocyte after its release into the peripheral blood.

The *in vitro* synthesis of heme by avian erythrocytes has been utilized to determine the precursors which participate in the biosynthesis of protoporphyrin. It has been found, using C^{14} labeled compounds, that both carbon atoms of acetic acid, the carbonyl carbon of pyruvic acid, and the methylene carbon of glycine are utilized in the synthesis of the carbon skeleton of protoporphyrin (68). The utilization of the amino group of glycine for the synthesis of both types of pyrrole rings of protoporphyrin has been demonstrated by finding equal N^{15} concentrations in the two pyrrole types which were obtained by appropriate degradation of hemin formed following N^{15} glycine feeding (69).

The biosynthesis of porphyrins and bile pigment has been investigated in a patient with congenital porphyria who excretes large amounts of uroporphyrin I and coproporphyrin I. Shortly after the feeding of N^{15} labeled glycine, very high concentrations of N^{15} were found in the coproporphyrin I, uroporphyrin I and stercobilin (65). These findings indicate that glycine is specifically utilized in the biosynthesis of porphyrins of the I isomer configuration as well as of protoporphyrin IX which is of the etioporphyrin III isomer configuration. They furnish additional evidence in support of earlier observations (64) that bile pigment is derived in part from one or more sources other than the hemoglobin of mature circulating erythrocytes.

CONCLUSION

Despite the relatively short period of time during which isotopes have been available, tracer techniques have exerted a pervasive influence on biochemical thought and practice. A definitive evaluation of this influence may have to await more extensive development of isotope investigation. It is possible, however, to indicate the two principal developments in biochemical thought which have already occurred and are due in part to the impact of tracer techniques.

Tracer studies have helped to develop a concept which provides insight into the mechanisms of biological synthesis. It has become evident that complex organic substances to a large extent are synthesized not from compounds of similar complex configuration but rather from small compounds of simple structure. The extensive participation of glycine and acetic acid in biosynthetic processes has focussed attention on the biochemical versatility and significance of small simple compounds.

The outstanding contribution of isotope methodology to biochemical thinking has been the development of the concept of the dynamic state of the body constituents. The experimental basis and theoretical implications of this concept, which includes an appreciation of the kinetics of biochemical reactions, represent a major advance toward a thorough understanding of the processes which occur in the living cell.

DOSAGE DETERMINATION IN THE USE OF RADIOACTIVE ISOTOPES

By LEONIDAS D. MARINELLI¹

(From the Physics Department, Memorial Hospital, New York City)

INTRODUCTION

As commonly used, most radioactive isotopes are ingested or injected in soluble form and subsequently deposited with a greater or lesser degree of selectivity in various cells and organs. In the event of a single administration, the number of radioactive atoms present at any particular site will increase at first (as they are drawn from the circulation along with their stable isotopes), it will reach a maximum and, as the source of supply becomes exhausted, it will decrease on account of both metabolic turnover and radioactive decay. The latter is accompanied by the release of ionizing radiation, the type and emission rate of which is the exclusive characteristic of the radioelement itself.

The direct measurement of radiation released in this manner in terms of units already established in Radiology is beset with numerous difficulties of experimental nature. Nevertheless when the physical factors of half life and radiation energy, and the physiological factors of uptake and excretion, are known, it is possible, in some cases at least, to make satisfactory estimates of tissue dosage.

The roentgen, as defined by international agreement, applies only to x- or gamma radiation; it can therefore be used for gamma ray emitting isotopes but not for radiation due to primary beta particles. (The roentgen is defined as "that quantity of x- or gamma radiation such that the associated corpuscular emission per 0.001293 gram of air produces, in air, ions carrying one e.s.u. of quantity of electricity of either sign.")

On the other hand if the energy absorbed per gram of air per roentgen (~ 83 ergs) is made the unit of energy absorption for beta rays, it is possible to establish a comparable basis for beta ray dosage. To be sure, in going from air to tissues certain corrections will have to be made because the energy absorption in tissue per roentgen exposure of x- and gamma rays depends

on both tissue composition and radiation wavelength, but in practice, for soft tissues, these corrections are not very large. Hence it is possible to define an "*equivalent roentgen*" as "that amount of beta radiation which, under equilibrium conditions, releases in one gram of air as much energy as one roentgen of gamma rays." Since the accepted symbol for the roentgen is "r," it is convenient to designate the equivalent roentgen by "e.r." (This is essentially the same unit as the "rep" or "roentgen equivalent physical" of the Plutonium Project.) In the present paper, formulae expressing the relationship between radiation dose and isotope concentrations are presented and their clinical applications discussed by the use of tables containing a considerable amount of pertinent information. Examples of application of the formulae to specific isotopes and definite problems will also be given. For the mathematical and physical aspects of the problem the reader is referred to the literature (1, 2).

CALCULATIONS

Beta Ray Emitters. When a radioisotope emits only beta rays, the dose is essentially confined to the regions containing the material because the range of the beta particles in tissue is only a few mm. Many organs in small animals used in experiments dealing with isotopes emitting high-energy beta rays are not small in comparison to the range of the beta particles. Proper estimate of the dose in these instances is, in general, very complicated, and must be left to the future.²

The total dose D_β , in equivalent roentgens, due to the complete disintegration of a radioelement biologically stable and present in a uniform concentration of C microcuries per gram of tissue is

$$D_\beta = K_\beta C \text{ e.r.} \quad I$$

where

$$K_\beta = 88 \bar{E}_\beta T \text{ e.r. per } \mu\text{cd.}^2 \text{ per gram;} \quad Ia$$

T is the half life of the isotope in days and \bar{E}_β the average energy per disintegration of the beta rays in million electron volts (Mev).

² This problem is somewhat similar to the problem of gamma emitters (*vide infra*).

³ $\mu\text{cd.}$ —microcuries destroyed, i.e., microcuries completely disintegrated in the tissue.

¹ On leave of absence to the Argonne National Laboratory, Chicago, Ill.

Doses per hour and per day are respectively

$$\begin{aligned} d_{\beta}(\text{hour}) &= D_{\beta}f_h \\ d_{\beta}(\text{day}) &= D_{\beta}f_d \end{aligned}$$

II

where f_d and f_h are the fractions of the entire quantity of

the isotope which disintegrate per hour or per day respectively. Values of T , \bar{E}_{β} , K_{β} and f_d are given in Table I which refers to beta ray emitters. Z is the atomic number and A the atomic weight of the elements given in the first

TABLE I

Physical data pertaining to calculations of radiation dosage resulting from beta rays and/or very soft x-ray radiation

The values of K_{β} and S_{β} are based on uniform and biologically stable concentrations of radioelements distributed in tissues of linear dimensions large as compared to the range of the beta particles. The sign "0" under the heading "Radiation" indicates the absence of nuclear gamma rays.

\bar{E}_{β} is the average energy per disintegration.

$K_{\beta} = 88\bar{E}_{\beta}T$ is the radiation dose expressed in equivalent roentgens due to beta rays emitted during the complete disintegration of 1 μ c of radioelement per gram of tissue.

$f_d = (1 - e^{-0.693/T})$ is the fraction of the entire quantity of isotope which disintegrates in 24 hours.

$S_{\beta} = \frac{100}{K_{\beta} \times f_d}$ is the concentration of radioisotope expressed in μ c per kg which will deliver a dose of 0.1 e.r. to tissue during the first 24 hours of exposure.

TABLE II

Physical data pertaining to calculations of radiation dosage resulting from gamma rays

Element	Z	A	Radiation	T Half life in hours	E _γ in Mev			I _γ at 1 cm mr/μc-hr r/mc-hr	K _γ at 1 cm r/μcd	f _d fraction disintegr. per day	μ per cm ×100

The sign "0" under the heading "Radiation" indicates the absence of nuclear gamma rays. The column headed "Annihilation radiation" refers to positron-electron recombination, the column headed "Nuclear gamma radiation" refers to gamma rays originating in the disintegrated nucleus. The numbers in parentheses indicate the number of photons of the particular energy that are released per disintegration.

In Group B, the numbers in square brackets pertain to x-ray emission following electron capture and, because of the short range of the radiation, they should not be used in computing γ-ray dosage. In practice, this type of dose computation is amenable to the simpler formulae used for β-rays (see Group C in Table I).

I_γ is the exposure in roentgens at 1 cm distance in air from an unfiltered point source of 1 mc, for one hour; or milli-roentgens per microcurie-hour (see formula IIIa).

K_γ = 1.44I_γ × 10⁻³ is the number of roentgens, per microcurie destroyed, at 1 cm distance in air from an unfiltered point source.

f_d = (1 - e^{-0.693/T}) is the fraction of the entire quantity of isotope which disintegrates in 24 hours. (T is the half life in days.)

μ = true absorption coefficient of the γ-radiation in water.

column. The last column gives the ranges in water for the most energetic beta particles of each beta ray spectrum for the different isotopes. It should be noted that the column for K_β gives immediately the dose in equivalent roentgens for each microcurie completely disintegrating within a gram of tissue.

Gamma Ray Emitters. When a substance is a gamma ray emitter, the problem of dosage determination is more complicated. The rays released in a given gram of tissue produce only a small amount of ionization there; most of their energy is expended elsewhere along their paths. The problem becomes somewhat analogous to that of interstitial radium gamma ray dosage, except that instead of discrete sources one is confronted with extended ones.

At a given point the *total dose* D_γ, due to gamma rays emitted by the complete disintegration of a radioelement biologically stable and present in a uniform concentration of C microcuries per gram of tissue, is given by

$$D_{\gamma} = K_{\gamma} C g \text{ roentgens}$$

III

where

$$K_{\gamma} = 1.44 I_{\gamma} \times 10^{-3} \quad \text{IIIa}$$

The dose delivered in one day is

$$d_{\gamma}(\text{day}) = D_{\gamma} f_d, \quad \text{IV}$$

f_d having the meaning expressed above. K_γ expresses the number of roentgens at 1 cm distance in air due to the *complete disintegration* of an unfiltered point source of 1 μc; 1.44 × t is the average life in hours, I_γ the dose-rate in roentgens per hour at 1 cm in air from an unfiltered point source of 1 mc. The quantity g in equation III is a *geometrical factor* depending on the location of the given point, the size and shape of the tissue mass containing the isotope, and on the absorption coefficient μ of the gamma rays in tissue. The values of I_γ and K_γ together with other pertinent information for gamma ray emitting radioisotopes are given in Table II.

Safe Tracer Concentration. In the main Tables I and II are self explanatory. Atten-

tion should be directed to column 9 in Table I, headed S_β , which indicates the "safe tracer concentration," that is, the number of μc per kg of tissue weight which will result in a whole tissue dose of 0.1 r the first day, due to the beta rays alone. (The gamma ray contribution will be discussed below.) In the case of a short-lived element, the dose on succeeding days will quickly decrease to the vanishing point, while for long-lived substances it will continue at an appreciable level for some time. This criterion of "safe dose" is decidedly conservative. One might prefer to choose such a level as 1 r in 10 days or some other value based on a longer period of time. This might avoid complications due to various half lives. However, the present familiar idea of safety is based on daily dose; hence that has been used here. It is not to be assumed that larger tracer doses should never be administered. It is sometimes entirely justifiable to use considerably higher doses in diagnostic problems.

Distribution of the Radiation in Tissue. The physical data presented enable the experimenter to calculate the actual dose delivered to a tissue

FIG. 1. RADIATION DOSAGE DUE TO THE BETA RAY ACTIVITY OF P^{32} IN DIFFERENT TISSUES IN MICE AS A FUNCTION OF TIME

The points marked on the right margin are the actual tissue doses obtained by extrapolation to infinite time. Theoretical whole animal dose equals K_β times the number of microcuries administered divided by the total weight of the animal.

or individual whenever the isotope concentration C is known as a function of time. This depends on the amount of isotope administered, the species and metabolic state of the test animal, the mode of administration, the chemical form under which the radioelement is given, etc.

Physiological information of this nature is of great importance; the literature shows that a good deal of animal work has been done on the relative uptake of various isotopes by different tissues at different times. As an example, in Figure 1 are shown the relative radiation doses delivered in different tissues in mice injected intraperitoneally with P^{32} in the form of Na_2HPO_4 . The animals were sacrificed at various times after the administration of the material, and the concentration of P^{32} was determined for the various tissues and organs. By adding graphically the daily doses as expressed by equation II it was possible to calculate the dose of radiation received by each tissue as a function of time (3). Similar calculations were made for the whole body assuming uniform distribution. The "theoretical" whole animal dose⁴ after complete disintegration of the isotope was taken as 100 per cent, and all other tissue doses referred to this value. Thus at the end of three weeks, 64 per cent of the theoretical complete dose had been delivered; but all tissues tested, except the bone, had received already practically all their radiation because most P^{32} had disappeared. The liver, for example, had received about 33 per cent of the theoretical uniform dose. At that time the bone had received 39 per cent; but in the bone the dosage increased to 48 per cent at the end of 36 days.

No tissue actually attained the theoretical dose or would have attained it after longer periods of time because of biological elimination. From the curves, the actual tissue dosage per μc of P^{32} thus administered in a mouse of 25 grams can now be calculated. The total animal concentration would be $0.04 \mu\text{c}$ per gram and the "theoretical" total animal dose $D_\beta = K_\beta \times 0.04 = 885 \times 0.04 = 35.4 \text{ e.r.}$ (K_β from Table I). The liver, then, at the end of three weeks would

⁴ By "theoretical" whole animal dose is meant the dose D_β which would have been obtained in the animal after complete disintegration of the isotope on the assumption of uniform concentration in the animal and of total lack of biological elimination.

have received 33 per cent of this value or 12 r; similarly the bone at 36 days would have had $0.48 \times 35.4 = 17$ r.

It is recognized that with P^{32} in mice these determinations are not as accurate as one would wish because the linear dimensions of most organs are smaller than the range of a considerable portion of the beta particles emitted by P^{32} . Similar information in larger animals would yield more reliable figures. Conversely this type of calculation would be fairly accurate even in a small animal, as the mouse, if soft beta ray emitters (H^3 , C^{14} , S^{35} , etc.) were used.

When working with humans it is not possible in general to study concentrations throughout the body and their variations with time by *in vivo* measurements; the extreme concentration of iodine in the thyroid is an exception. For most isotopes information must be obtained from biopsy and autopsy measurements and hence the data are meager; moreover they are scattered through various publications which were often not prepared with this point in mind. Accordingly it has happened too often that the published results lack some essential fact, such as the actual weight of the individual. It is to be hoped that more of this information will be forthcoming. In the meanwhile, it is wise to adopt a conservative attitude in dealing with humans whenever physiological information is lacking. This can be done by assuming that no biological elimination takes place.

Differential Absorption Ratio. To take into account the differences in uptake which lead to differences in dose for the various tissues, it is convenient to express the concentration in terms of a "differential absorption ratio" (D.A.R.). For any tissue, this is the ratio of concentration of an isotope in that tissue to the average concentration in the body (neglecting excretion). Thus under the assumption just made if a particular tissue has a D.A.R. of 1, it receives the same dose of radiation as the average of the whole body. On the other hand, if it has a D.A.R. of 10, it receives ten times as much radiation as the average.

In calculating the safe doses for tracers, it is highly desirable to have some idea of the *range* of the D.A.R.'s. The safe dose is assumed to be 0.1 per day for the entire body; if a certain

tissue has a D.A.R. of 10, it would have received 1 r while the rest of the body received 0.1 r. This might lead to undesirable irradiation of certain tissues or organs from a dose believed safe otherwise.

The procedure outlined above needs clarification. In general, single tissues and the whole body have different rates and modes of elimination; hence the tissue D.A.R. will vary with time. The question then arises as to the time at which D.A.R.'s have significance in determination of tissue dosage. Evidently the D.A.R. will be too low when taken too soon after the isotope administration because the concentrations have not yet stabilized. Likewise adoption of the D.A.R. after several half lives will have little or no significance because most of the isotope has disintegrated. One useful index, whenever the isotope reaches the body tissues through the circulatory system, could be the stabilization of the plasma concentration. No general rule, however, can be given and good judgment is of paramount importance.

Effective Half Life. In instances of extreme concentrations as in the case of *radioiodine* I^{131} administered to humans in the form of KI or NaI, greater accuracy can be obtained. It will be noted that the formula I for the dose, D_B , contains the half life of the element. If the amount of iodine in the gland decreases both by decay and by excretion, the *effective half life* will be less than the physical. Such effects can be determined only by actual measurements. In this particular problem, counts are made at intervals with a Geiger counter in a fixed position over the thyroid gland. If there were no excretion of the material from the gland, these counts should decrease exactly in accordance with the physical decay curve for the iodine; that is, for I^{131} they should be at half their initial value after eight days, one-fourth at 16 days, etc. Actually, they decrease exponentially but more rapidly, half lives as short as two days having been encountered in practice. It is evident that the use of this number instead of 8 in equation I results in a decrease of 75 per cent in the administered dose, an amount which is clinically significant in therapeutic work. It would be now possible to calculate from formula I the dose delivered under normal conditions if the

initial concentration C were known. This can be determined either by actual biopsy or "guessed" by estimate of the gland weight and measurements of the radioactive content of the gland by proper *in vivo* observations.

It is evident from Table I that the actual amounts of the *safe concentrations in tissue* do not vary very greatly; it must be realized that the intervals at which they can be repeated do. A reasonable interval between full tracer doses of any particular element would be four or five half lives, unless the material has been shown to be excreted fairly completely in a shorter period. If no significant excretion occurs, a tracer of Na^{24} could be repeated within about three days, while P^{32} should not be repeated in less than about two months, and Ca^{45} not before two years have elapsed.

It should be mentioned in this connection that the safe doses listed here are calculated on the assumption that the individual is receiving no radiation from any other source. Extensive radiographic or fluoroscopic procedures may result in an appreciable dose of radiation, and such possibilities must not be overlooked.

TRACER ISOTOPES—EXAMPLES

In order to illustrate the use of the material presented in this paper sample calculations will be given for some isotopes commonly used in tracer experiments and in therapy. These will be presented in order of the complexity of their spectra.

Radioactive phosphorus— P^{32} —(Beta particles only)

If the isotope were evenly distributed throughout the body and no elimination took place the values of Table I would be directly applicable. Thus, if $2.4 \mu\text{c}$ per kg gives a dose of 0.1 e.r., an initial radiation dose of d e.r. per day will require a concentration $x \mu\text{c}$ per kg such that

$$2.4:0.1 = x:d,$$

namely:

$$x = 2.4d/0.1 = 24d \mu\text{c per kg}.$$

If a total radiation dose D_β (e.r.) is to be given to a tissue, the concentration in that tissue should be such that

$$D_\beta = K_\beta C \quad \text{or} \quad C = D/885 \mu\text{c per gram}.$$

As already mentioned, the most exhaustive

information on the distribution of this isotope in mice (3) shows that the highest radiation dose is given to bone, followed in order by spleen, liver, kidney, muscle and blood. In general, the limited information on adult humans obtained for the major part from autopsies of leukemic patients (4–9), does not contradict the results in mice, provided that only non-infiltrated tissue obtained from patients given single doses of P^{32} be taken into consideration. Limited data on non-irradiated surgical material are also available (10). The most reliable D.A.R.'s on bone are of the order of unity though wide variations are noted not only among individuals but also among portions of the same bone (5, 10). The absolute value of the D.A.R.'s for human bone—as in the case of mice—seems to bear no detectable relation to the time elapsed between administration and assay; this points to a slow "net" elimination of P^{32} from bone.

The highest D.A.R. reported on human marrow (7, 10) devoid of *leukemic infiltration* can also be taken of the order of unity for the first few days following P^{32} administration. Data on sternal aspiration (7), however, are decidedly lower, being much closer to that of blood. The latter in humans receives "apparent" doses of the order of 20 per cent of the theoretical whole body dose (11). It seems therefore that doses of the order of $2.4 \mu\text{c}$ per kg of body weight can be safely administered, though they may produce wholly transitory but definite biological effects, such as those reported by Low-Beer and Treadwell (12) for concentrations of 6–9 μc per kg of body weight.

If P^{32} is administered intravenously in *insoluble form* the deposition in the liver and spleen is likely to be very marked (13). The authors report 80–89 per cent in the liver (dog and mouse); if this were to obtain in humans the D.A.R. would be:

$$\text{D.A.R.} = \frac{\frac{\mu\text{c in liver}}{\text{liver weight}}}{\frac{\mu\text{c administered}}{\text{body weight}}} = \frac{0.89 \times 70}{1.7} = 36.7,$$

1.7 kg being the weight of the average human liver (14). In this case the maximum permissible concentration would be

$2.4/36.7 = 0.066 \mu\text{c per kg of body weight}$
or a total tracer dose of $0.066 \times 70 = 4.6 \mu\text{c of } \text{P}^{32}$ for a 70 kg man.

Radioactive strontium—Sr⁸⁹—(beta particles only)

Work on animals (15) indicates that this isotope is *highly concentrated in the bone*. Human material has been reported by Treadwell *et al.* (16) following intravenous injections. Their data point to a maximum D.A.R. in the epiphysis of bone of 13.2, and an unweighted average of 8.3 for bone, mostly in young subjects. A trend of D.A.R. change with time is not apparent. On the basis of this, the tolerance concentration would be, since $S_\beta = 3 \mu\text{C per kg}$, $S_\beta/8.3 = 3/8.3 = 0.4 \mu\text{C per kg of body weight}$.

Radioactive calcium—Ca⁴⁵—(beta particles only)

The relative concentrations of this isotope in human tissue have not been reported to date. Work on mice shows that the D.A.R. for Ca in animal bone is approximately twice that for Sr (15). Hence, if this ratio holds also for humans one should expect a D.A.R. of about $8.3 \times 2 = 16.6$.

It follows from Table I that the tolerance concentration would be, since $S_\beta = 16 \mu\text{C per kg}$,

$$16.0/16.6 \approx 1.0 \mu\text{C per kg of body weight}.$$

It should be noted that if calcium were deposited exclusively in the human skeleton and the distribution were uniform the D.A.R. would be 10 (weight of skeleton = 10 per cent of body weight); nevertheless, the most active parts of the bone concentrate it more and hence the higher value adopted is not unreasonable.

Radioactive sodium—Na²⁴—(beta and gamma radiation)

This isotope of sodium, administered orally or intravenously, is eliminated in very small amounts during times comparable to its half life. Since it is distributed rather uniformly throughout the body (17, 18), computation of beta ray dosage can be made on the basis of D.A.R. = 1. The factor S_β of Table I can be applied directly in the case of small animals where the beta rays account for most of the radiation dose, the factor g in the gamma ray formula being very small. For larger animals and humans, however, the gamma ray contribution cannot be neglected. In this case dosage calculations become more involved.

As pointed out above the contribution of gamma rays to the daily tissue dose is

$$d_\gamma = C_\gamma K f_d g \text{ roentgens where}$$

C = concentration in $\mu\text{C per gram of tissue}$

K_γ = roentgens at 1 cm per μC

f_d = fraction of atoms destroyed in one day

g = geometrical factor which is a function of the size and shape of the tissue volume and the penetration of the radiation.

For purposes of calculation one may assume that the human trunk is a cylinder of radius $R = 20 \text{ cm}$ and height $2Z = 60 \text{ cm}$, and that C is constant throughout. Under these conditions the highest dose is delivered at the mid-point of the axis and g can be expressed with sufficient approximation (1) as $g = 314 - 4140 \mu$ where μ is the absorption coefficient of the gamma rays in tissue. For the gamma rays from sodium (see Table II) the values of μ are 0.0296 and 0.0233 per cm, respectively. An average $\mu = 0.025$ may be assumed for the present calculation and hence $g = 210.5$. Substituting for K_γ and f_d the values from Table II, one obtains:

$$d_\gamma = 0.40 \times 0.68 \times 210.5 C = 58.0 C \text{ r per day at the center of the trunk if } C \text{ is given in } \mu\text{C per gram of tissue}.$$

Similarly (Table I):

$$d_\beta = 29 \times 0.68 \times C = 19.7 C \text{ e.r. per day if } C \text{ is given in } \mu\text{C per gram of tissue}.$$

Hence the total dose for the first day is $d_{\beta+\gamma} = 77.7 C$. The total dose $D_{\beta+\gamma}$ can be obtained from this figure. Since 68 per cent of the atoms disintegrate during the first day, 77.7 C is 68 per cent of the total dose. Hence the latter is:

$$D_{\beta+\gamma} = \frac{100}{68} \times 77.7 = 114 C \text{ e.r.}$$

For the tolerance dose of 0.1 r per day,

$$S_\beta = \frac{0.1}{77.7} = 0.0013 \mu\text{C per gram}$$

or 1.3 $\mu\text{C per kg of body weight}$.

Radioactive sodium—Na²²—(beta and gamma radiation)

The computation of tolerance dose follows closely that illustrated for Na²⁴ except for the numerical values involved. Thus, $K_\gamma = 500$; $f_d = 6.3 \times 10^{-4}$; $g = (314 - 4140 \times 0.032) = 181$, since μ can be considered to be 0.032 for the purpose of this approximation.

Hence,

$$d_\gamma = 500 \times 6.3 \times 10^{-4} \times 181 = 57 C \text{ at the center of the trunk and}$$

$$d_\beta = 22,000 \times 6.3 \times 10^{-4} \times C = 14 C$$

$$d_{\beta+\gamma} = 71 C \text{ e.r. per day if } C \text{ is in } \mu\text{C per gram of tissue}$$

$$D_{\beta+\gamma} = 11.3 \times 10^4 C \text{ e.r.}$$

$$S_{\beta+\gamma} = \frac{0.1}{71} = 0.0014 \mu\text{C per gram} = 1.4 \mu\text{C per kg of tissue}$$

or body weight since C is considered constant throughout the body.

This dose ($D_{\beta+\gamma}$) would be delivered over a period of years if there were no excretion of the sodium. However, experimentally the material has a physiological (or effective) half life of the order of one month or less, in normals and in individuals with congestive heart failure (19). In these cases the actual $D_{\beta+\gamma}$ is nearer to 3,000 C. For nephrotics excretion is very much slower, and the dose of radiation would be correspondingly larger.

These two sodium isotopes offer a good illustration of the point made above regarding the repetition of tracer doses. Although the doses of the two isotopes which will give 0.1 e.r. the first day are essentially the same, the total dose from this amount of Na^{24} may be repeated much sooner.

Radioactive potassium— K^{42} —(beta and gamma radiation)

Under the same assumptions of distribution and elimination as in the case of Na^{24} ,

$$K_{\gamma} = 0.0348, f_d = 0.739 \text{ and } g = 198$$

$$d_{\gamma} = 0.035 \times 0.74 \times 198 \times C = 5.2 \text{ C at the center of the trunk, } d_{\beta} = 63 \times 0.74 \times C = 46.5 \text{ C}$$

hence

$$d_{\beta+\gamma} = 51.7 \times C \text{ e.r. per day (C in } \mu\text{C per gram)} \\ D_{\beta+\gamma} = 70 \text{ C e.r.}$$

and finally

$$S_{\beta+\gamma} = \frac{0.1}{51.7} = 1.9 \mu\text{C per kg of body weight.}$$

Radioactive iodine— I^{130} —(beta and gamma radiation)

The distribution of radioiodine in the body is characterized by a *high and relatively stable deposition in normal thyroid tissue* and a low concentration in the rest of the body.

Assays in rabbits and rats (20) show that at various times after administration of iodide, most known radiosensitive tissues show average concentrations of the isotope close to that of blood. Unfortunately no information is available for the marrow. The concentration in thyroid tissue, however, is so markedly different from the rest of the body that the dosage problem assumes different aspects according to whether tracer studies or radical therapeutic procedures are contemplated. Full discussion of the latter is outside the scope of the present paper (21, 22).

In the case of tracer studies it is of interest to calculate the dose to the thyroid itself, since it is very unlikely that the radiosensitivity of any other tissue in the body is such as to overcome the very large thyroid D.A.R. From Table I the beta ray daily dose is readily calculated.

$$d_{\beta} = 12.4 \times 0.73 \times C = 9.1 \text{ C}$$

For the calculation of D_{γ} , from Table II $K_{\gamma} = 0.237$; $f_d = 0.73$. The geometrical factor g is very different from the cases of sodium and potassium in which the whole body dosage was considered. The usual gland (about 25 grams) can be represented by two separate spheres of radius equal to only 1.4 cm and, for this calculation, we may neglect the influence of the radiation from one lobe on the other. In this case $g = \frac{4\pi(1 - e^{-\mu R})}{\mu} \sim 4\pi R$ = 17.6 since μR is very small. It follows that

$$d_{\gamma} = 0.237 \times 0.73 \times 17.6 = 3.0 \text{ C}$$

at the center of the lobe. Hence

$d_{\beta+\gamma} = (3.0 + 9.1) \text{ C e.r. per day, C being in } \mu\text{C per gram of thyroid weight.}$

$D_{\beta+\gamma} = 16.6 \text{ C e.r. and } S_{\beta+\gamma} = 0.1/12.1 = 0.0083 \mu\text{C per gram of thyroid weight. For a 25 gram thyroid this would mean } 0.0083 \times 25 = 0.2 \mu\text{C of } I^{130}.$

Radioactive iodine— I^{131} —(beta and gamma radiation)

Following the same pattern used for I^{130} ,

$$d_{\beta} = 127 \times 0.08 \times C = 10.5 \text{ C}$$

and $d_{\gamma} = 0.66 \times 0.083 \times 17.6 \sim 1.0 \text{ C at the center of the lobe; hence}$

$d_{\beta+\gamma} = 11.5 \text{ C e.r. per day if C is in } \mu\text{C per gram of thyroid weight.}$

$D_{\beta+\gamma} = 139 \text{ C e.r. (if there is no elimination).}$

As to the tolerance dose, $S_{\beta+\gamma} = 0.1/11.5 = 0.0087 \mu\text{C per gram of thyroid; for the whole gland (25 grams) this would mean } 0.22 \mu\text{C of } I^{131}.$

These doses, which deliver 0.1 r to the gland and less than one per thousand of this to the entire body, are obviously well below the accepted tolerance dose to the *whole* body. They correspond to oral or intravenous administration of 0.2 to 2 μC per patient (to account for excretions of 10 to 90 per cent), and are sufficient for excretion studies as well as for assay of surgical biopsy material. They are, however, insufficient for radioautography with thin tissue sections, for extended studies of blood concentrations and for *in vivo* investigations of iodine retention by thyroid tissue by means of external detectors except, possibly, when scintillation counters are used.

Studies on blood concentration and *in vivo* measurements would require doses of the order of five to 20 times those calculated (thyroid doses of 4 to 15 e.r. in about three weeks, if I^{131} is used, taking into account elimination by the organ, and only .4 to 1.5 e.r. in two days for I^{130}). Autoradiographic material can be obtained only with minimal concentrations of the order of several μc per gram of thyroid tissue (23). It seems therefore that in benign conditions, doses permitting excretion and tissue assays, blood concentration and *in vivo* measurements can be expected to produce no untoward effects, since the radiation is limited for a relatively short time to a very small part of the body which is not particularly radiosensitive. However, in the case of radioautographs, when radiation therapy or total thyroidectomy is not contemplated, every effort should be made to obtain them with the fastest film and low photographic density (23).

At this point it is well to consider that when tracer studies are to be carried out once or a few times on an individual, for diagnostic purposes, the physician may legitimately employ doses considerably in excess of those giving only the radiation permitted for continuous exposure. The diagnostic radiologist does not hesitate to give local exposures of several roentgens, and to repeat these at need. The justifiable dose in such cases must be determined by the clinician responsible for the patient.

The above examples illustrate the fact that no general statement can be made regarding the relative importance of the beta and gamma ray contributions to dosage. In the first place, the relative amount of energy emitted in the form of beta and gamma rays varies from one isotope to another. Also the geometrical factor g , which is a function of both penetration of radiation and size of organ, is likely to vary tremendously with the problem, as in the cases of sodium and iodine.

MISCELLANEOUS FORMULAE

The weight of one millicurie of carrier free isotope can be readily calculated by noting that the weight of an atom of an element of atomic weight A is $(A/N) \times 10^3$ mg where $N = 6.02 \times 10^{23}$, Avogadro's number. Since 1 mc of an isotope contains $1.44 \times T \times 3.7 \times 10^7 \times 8.64 \times 10^4$ atoms (T in days) it follows that the weight of 1 mc = $1.44 \times 3.7 \times 10^7 \times 8.64 \times 10^4 \times 10^3 \times A \times T / 6.02 \times 10^{23} = 7.65$

$\times 10^{-9} \times T \times A$ mg. Values derived from this formula for the various isotopes are presented in Table I, column 10.

It seems of interest to close this paper with an illustration of the weights of radioelements necessary to produce marked radiation effects. This can be done by the following considerations. In order to deliver 1 e.r. to a tissue by means of a beta ray emitting isotope a concentration C is required such that

$$C = 1/88\bar{E}_\beta T \mu\text{c per gram of tissue.}$$

In terms of weight

$$C = 7.65 \times 10^{-12} \times 10^{-3} \times A \times T / 88\bar{E}_\beta T = 8.7 \times 10^{-17} A/\bar{E}_\beta \text{ gram per gram of tissue.}$$

As an example, for P^{32} , $A = 32$; $\bar{E}_\beta = 0.7$ Mev; hence for a lethal whole body dose of 1,000 r the concentration required is $C = 8.7 \times 10^{-17} \times 32 \times 10^3 / 0.7 = 3.98 \times 10^{-12}$ gram per gram of body weight (a total of 0.28 μg for a 70 kg man). Since phosphorus constitutes only 1.14×10^{-2} of the weight of the human body (24) only one atom in 2.85×10^9 atoms of phosphorus need be replaced on the average to obtain such an effect, on the assumption that no elimination takes place.

SUMMARY

When radioactive isotopes are employed either as tracers or in therapy, it is important to be able to determine the radiation dosage. This cannot, in general, be measured, but when the half life, radiation energy, and biological uptake and excretion are known, it can be calculated.

Since the basic information regarding radiation disintegration schemes and energies is scattered through many journals, it has been considered desirable to collect pertinent data. Two extensive tables are presented, for beta and gamma rays respectively, giving half life, radiation average energy, fraction disintegrating per day, and specific dosage data, including the safe tracer concentration, for some 33 isotope elements.

PERSONNEL PROTECTION IN THE USE OF RADIOACTIVE ISOTOPES

By G. FAILLA

(From the College of Physicians and Surgeons, Columbia University, New York City)

Artificially produced radioactive isotopes are distributed by the Atomic Energy Commission according to strict rules on account of the dangers inherent in the handling of such materials. Before an individual can obtain radioisotopes, he has to present evidence that he possesses the knowledge, facilities and equipment to meet the minimum standards of safe handling. The Isotopes Division in Oak Ridge, Tennessee, is anxious to help the users in matters of protection and makes available to them articles or pamphlets on this subject, as well as expert advice. It may be assumed, therefore, that the reader is familiar with recent publications on the subject or may get the available information by simply asking for it. Also, a comprehensive report on "Safe Handling of Radioactive Isotopes and Fission Products" is being prepared by the National Committee on Radiation Protection, and will soon be ready for distribution. Accordingly, in the present article no attempt will be made to cover the whole subject, and in fact only a few topics will be discussed, which in the opinion of the writer deserve special emphasis.

The mental attitude of the worker plays an extremely important part in the problem of protection. Most people who have received some cursory instruction, are very careful at the start. Sooner or later a minor "emergency" arises and the individual decides that it is necessary to disregard some rules. The "emergency" might consist simply in not having allowed enough time for the preparation of a sample to be used on a patient at a specified time. Perhaps the surgeon is waiting for the material in the operating room. To save time, the worker then goes through the necessary manipulations without using the protection devices provided for the purpose. For some time thereafter, he might be a little apprehensive and think that perhaps he got too large an exposure. However, unless the exposure was really excessive, he cannot detect any ill effects from it and after a few such experiences he is apt to conclude that the danger of overexposure has been

exaggerated, or that perhaps he is particularly resistant to radiation.

Every worker must be made to realize that radiation injury may not become apparent or serious for many years. This is true even in the case of a single exposure or a few exposures taking place within a matter of weeks. Recently the writer heard of a case in England in which cancer of the skin developed 40 years after the patient had been treated with X-rays in the same region for another ailment. In numerous radiologists, and technicians, cancer of the skin of the hands has developed 15 to 25 years after they started to work with X-rays or radium, although the bulk of the exposure occurred during the first few years when the danger of radiation was not fully realized. The individual worker simply has no way of telling what constitutes a safe exposure from his own experience. By the time that some tissue damage becomes evident to him, it may be too late to do anything about it and eventually serious injury or death may result. Therefore, each worker should accept the permissible limits of exposure set by competent authorities and should strive by all possible means to keep his exposure well below these limits at all times.

In this connection it is well to point out that no matter how careful an individual may be, an occasional overexposure is apt to occur through some accident or through carelessness on somebody else's part. If the person has maintained his exposure well below permissible limits, he is in a better position to escape injury if such overexposures do occur through circumstances beyond his control. Furthermore, the worker should never exceed the permissible limits of exposure on the ground that after some definite date he will no longer work with radiation. Conditions may change and he may decide to continue working with radiation indefinitely. It is not good judgment to acquire a handicap needlessly.

People with considerable knowledge of the subject sometimes get in trouble by attempting to estimate the dosage rate in a region in which they are

anxious to work, on the spur of the moment and under great mental stress. It should be an inalterable rule never to venture into a potentially dangerous region without first surveying it *with the proper kind of measuring instrument known by actual test to be in good working order*. A region in which there is a source of ionizing radiation must be considered to be potentially dangerous, whether protective measures have been taken or not, until proven safe by proper measurements. In other words the worker must not decide that the protective measures are satisfactory by mere inspection, unless he is an expert in the field of protection.

In this connection, some common pitfalls will be mentioned. Lead bricks are usually available in a radioactivity laboratory. With these, temporary protective barriers are built up. Sometimes a single barrier is placed between the source and the part of the room that it is desired to protect. This may or may not be sufficient depending on the strength of the source and the radiation it emits. The lead thickness may be ample for radiation passing through it but radiation emitted in other directions will strike walls, etc., and will be scattered all over the room. More often the container rests on the table and lead bricks are placed around it. Again radiation emitted in the direction of the floor and towards the ceiling can be scattered throughout the room. It is always best to surround a gamma ray source with lead of sufficient thickness in all directions. When temporary barriers are set up, a radiation survey with an appropriate meter should be made to make sure that the dosage rate at all points of the working space is within permissible limits. Adjoining rooms should be surveyed too.

In making a survey for scattered radiation in the case of a source not completely surrounded by lead, it should be remembered that the dosage rate may be highest in regions located at considerable distances from the source. Thus all occupied space in the vicinity of a strong source should be surveyed. Ordinary survey instruments do not respond equally to radiation reaching them from different directions. Hence at any one point it is necessary to take readings with the instrument pointed in different directions to determine the maximum and to establish the cause in case additional protection is needed. It should be remem-

bered that floors and ceilings, as well as the walls, scatter radiation, and the instrument should be pointed downward and upward, too.

The preceding discussion is specifically applicable to gamma ray sources. In the case of materials emitting high energy beta rays (*e.g.*, P^{32}) scattered radiations must also be taken into account. In fact the danger of scattered beta radiation is more insidious because it is often unsuspected. Marked scattering of beta rays occurs *in air*, so the presence of solid bodies in the neighborhood of the source is not necessary to scatter beta rays into a region that might be assumed to be well protected. For example the beam of beta rays emerging through the mouth of an uncapped bottle containing a P^{32} solution, is scattered far beyond its geometric confines. In fact some beta rays from the beam will reach practically every part of a small room. The dosage rate at any one point will depend on the amount of P^{32} in the bottle, and on other obvious factors. In making a radiation survey in this case it is imperative to point the instrument in different directions because usually beta rays can enter the device only through one side, which is provided with a suitable window.

When large amounts of beta ray emitting material are involved, it may be necessary to provide protection against the X-rays ("bremsstrahlen"), produced by the beta rays in the material itself and in the container. The production of these rays is the same as that of X-rays in an X-ray tube, when the electrons impinge on the target. As is well known the higher the atomic number of the target material, the higher the X-ray output. Similarly, P^{32} in a lead container would produce a much higher intensity of X-rays than when placed in a glass bottle. Therefore, in the case of pure beta ray sources, shielding is best accomplished by the use of low atomic number materials. (This is the opposite of gamma ray shielding.)

It is generally assumed that isotopes emitting gamma rays are more dangerous to handle than pure beta emitters (from the point of view of external irradiation). This is obviously true because, for one thing, there is usually beta radiation of not negligible energy associated with the gamma rays. The main reason, however, is that in general the penetrating power of gamma rays is much greater than that of beta rays. Thus only

the superficial tissues of the body (to a depth of at most several millimeters) are irradiated by beta rays, whereas the entire body is traversed by gamma rays. In the case of external sources, eventual production of cancer of the skin and induction of leukemia constitute the principal hazards of exposure to ionizing radiation. With gamma rays both hazards are potentially present, whereas with beta rays (which do not penetrate to the blood forming organs) only cancer of the skin need be considered. Since leukemia is always fatal but cancer of the skin can be cured in a large percentage of cases, it is obvious that exposure to gamma rays is by far the more dangerous. However, this statement, which is true in general, must not be interpreted to mean that there is little danger involved in the handling of beta ray isotopes.

At the present time most university or hospital laboratories handle rather small quantities of radioactive isotopes. Reasonable care is exercised in storing these materials. Therefore, most of the exposure occurs in carrying out some manipulative procedure at close range with rather crude protective devices. Under such conditions the hands are exposed to much higher intensities of radiation than the rest of the body and the principal hazard is tissue damage in the hands that may lead to cancer of the skin later—no matter what kind of radiation is emitted by the material. In this respect and under existing conditions, therefore, the external irradiation hazard is not so different in the two cases (*e.g.*, unshielded equal amounts of P^{32} and I^{131}) as might be supposed. Hence the importance of handling P^{32} with great care also. There is an additional reason for doing so. Most workers handle more than one isotope and the total exposure of the hands from all sources must be considered. In the case of beta ray isotopes it is relatively simple to provide, or even improvise, handling devices that reduce the exposure of the hands to a low level, because the radiation can be completely stopped by light shields. It is, therefore, advantageous to do so, since then exposure to gamma rays (for which adequate protection is more difficult to provide) can be correspondingly greater.

The importance of taking great precautions in the handling of beta ray sources can be brought out best by numerical examples. The data given in

TABLE I

Dosage rates at different perpendicular distances from the surfaces of two radioactive preparations

Distance from surface	10 mc P^{32} solution in 10 cm ² dish (see text)	10 mg Ra tube applicator (gamma rays only) (see text)	Ratio P^{32}/Ra
cm	<i>e.r./hr</i>	<i>r/hr</i>	
0	740	450	1.65
1	300	41.6	7.2
2	112	14.4	7.8
5	31.1	2.77	11.2
10	9.94	0.785	12.7
25	1.80	0.131	13.8
50	0.43	0.033	13.0
100	0.084	0.0083	10.1

Table I will serve this purpose well in that comparison can be made with the more familiar problem of radium protection. First it is necessary to explain briefly how the data were obtained.¹ The dosage rate at the surface of the P^{32} solution (740 e.r./hr²) was determined by means of an extrapolation ionization chamber in which one electrode was the solution itself. By subsidiary experiments, a correction factor was determined to reduce the readings to what they would have been, had both electrodes been made of water. (The amount of phosphate in the P^{32} solution was entirely negligible.) The results are expressed in terms of the number of ion pairs produced per gram of air divided by the number of ion pairs corresponding to one roentgen, that is, 1.62×10^{12} per gram of air. This then is the e.r. as used here.

It should be noted that 740 e.r./hr is the dosage rate at the surface of the solution when it is in contact with the body (*e.g.*, the hand or even a finger),

¹ Details of the experiments and additional data will be published in the near future by the writer and Mr. Norman Bailey.

² In the absence of an internationally accepted unit of quantity of radiation applicable to all types of ionizing radiations, different authors have defined units such as the "equivalent roentgen" (e.r.), the "roentgen equivalent physical" (rep), etc., for dosage purposes. There is some confusion at present as to the definitions and magnitudes of these units, because different effects have been used to establish the "equivalence" with the roentgen. Sometimes the equivalence is based on the number of ion pairs produced per gram of air, at other times on the energy absorbed per gram of air or per gram of tissue. The difference in magnitude of these units is roughly 10-15%, depending on which ones are compared. The meaning of the e.r. as used here is explained in the text.

because the contribution of back-scattered beta rays was purposely included in the measurements. The dosage rates at different distances from the P^{32} source were measured with an extrapolation chamber in which the front electrode (graphited nylon film) had an equivalent thickness of 1.5 mg/cm². The back electrode of thick polystyrene provided essentially the same back scattering as soft tissue. Accordingly, the figures represent the dosage rates that would obtain at the surface of the skin at the different distances from the P^{32} source. In the case of the radium tube the dosage rate at the surface was determined by measurement with a cylindrical extrapolation chamber (1). The other values were calculated and do not include back scattering, which, however, is negligible for short distances.

The dosage rates given in the table are for the following sources: (1) Platinum tube containing 10 mg (10 mc) of radium, with a wall thickness of 0.5 mm and an active length of 12–14 mm, enclosed in a plastic sleeve having an outside diameter of 6.34 mm ($\frac{1}{4}$ inch). (2) "Thick" source consisting of 10 mc of P^{32} in water solution in a polystyrene dish with an area of 10 cm² and a depth of 1 cm (10 cc).

It is evident at a glance that the dosage rates for both sources are very high at short distances. A finger in contact with the surface of the P^{32} solution would receive 740 e.r. in one hour, 12.3 e.r. in one minute, or 0.205 e.r. in one second. A finger in contact with the radium applicator would receive about two-thirds of this dose in the same time. In comparing the values for the P^{32} solution and the radium applicator, the most striking thing is that the dosage rate produced by the former shows a marked increase *relative* to the radium applicator dosage rate, as the distance increases to 25 and even 50 cm. At a distance of 1 cm it is already 7.2 times greater than that of the radium tube and at 25 cm it is 13.8 times greater. This means that at a distance of 25 cm directly over the 10 mc P^{32} solution, the *surface* of the hand would receive, in a given time, the same amount of radiation that 138 mg of filtered radium would deliver at the same distance and in the same time. In other words, at this distance and *insofar as the surface of the skin is concerned*, the 10 mc P^{32} solution is "equivalent" to 138 mg of filtered radium. At 100 cm distance it is equivalent to 101

mg of filtered radium. This shows clearly that distance is less effective in decreasing the dosage rate of high energy beta ray sources than in the case of penetrating gamma rays. It will be seen further that the dosage rate is quite high even at a distance of 100 cm from 10 mc of P^{32} as a thick source—in which case most of the radiation is absorbed within the source itself. If the same amount of P^{32} had been evaporated to dryness in the same dish, the dosage rates for all distances would have been much higher.³ Therefore it is more dangerous to handle P^{32} as a thin dry film or deposit than as a thick source of dimensions comparable to the maximum range of the beta rays. It should be noted in this connection that radium in the form of a pure salt or in solution is very dangerous (more so than P^{32}), because of the large amount of high energy beta radiation which it liberates in addition to the gamma rays.⁴ The comparison is made here with sources such as are commonly used in radiological practice.

It is important at this point to reiterate that the dosage rates given in Table I relate only to the surface of the skin. They are directly applicable to the problem of protecting the skin but they give an exaggerated picture of the radiation hazard as a whole. The comparison with the gamma ray dosage rates of the radium applicator is particularly misleading in this respect. It was made in order to emphasize the importance of protection in the handling of P^{32} in hospital laboratories where familiarity with the handling of *filtered* radium might well lead to overexposure of the hands. One who has handled radium applicators for years might not realize that the skin of the hand would get very much more radiation from P^{32} sources of equal millicurie content. However, the overall danger is much greater in the case of radium because the gamma rays penetrate the whole body and can cause damage, with much more serious possible complications (leukemia). The most energetic beta rays of P^{32} are completely absorbed in 8 mm of tissue, and 2 mm of tissue reduce the

³ Experimental data obtained under these conditions will be published later.

⁴ It is well known that radium taken into the body is much more dangerous than P^{32} . In the present discussion only the danger of irradiation by external sources is being considered.

dosage rate of a thick P^{32} source in contact with the skin to about 10%.

Mention has already been made that in making a radiation survey in a laboratory, the proper kind of instrument should be used. This is particularly true in the case of beta rays. Since the main concern is the dose received by the skin, the instrument should be capable of measuring this quantity. At present, ionization chambers are best for this purpose. Obviously the window that admits the radiation into the chamber must be very thin.⁵ The walls of the chamber should be made of, or lined with, organic material in order that the contribution of scattered beta rays to the ionization current be essentially the same as that of living tissue. The thickness of this material should be sufficient to provide the maximum back scatter. One-half the range of the fastest beta rays to be measured, or approximately $\frac{1}{8}$ inch, is ample. It is desirable to make the chamber small and particularly shallow so that the readings would be representative of the dosage rate at the point of reference. Unfortunately, in the usual survey meters, large chambers are used to provide currents readily measurable by portable instruments. The calibration of these meters then presents a

⁵ The cells at the surface of the skin to a depth of perhaps 7 mg/cm² are considered to be non-reactive to reasonably large doses of radiation since they are practically "dead." A window of this thickness is satisfactory to determine the dosage rate at the depth of the presumably radiosensitive skin cells, when the ionization chamber is properly designed in other respects.

major problem. As a matter of fact, no such instrument can possibly read beta ray dosage rates correctly for all isotopes, all distances, and all shapes and sizes of source. The data of Table I may be used to advantage in calibrating beta ray survey meters for P^{32} sources similar to that described here and at various distances. It should be noted in this connection that the *area* of the source influences the reading considerably. Thus, maintaining both the depth of solution (1 cm) and the concentration (mc/cc) constant, the dosage rate at distances of 10 to 100 cm will increase approximately in proportion to the surface area, when the area is varied from 10 to 40 cm².

Time does not permit discussion of other topics. It may be well to state, however, that the National Committee on Radiation Protection has revised the permissible limits of exposure to ionizing radiation. The new values, of interest in the present connection, that will soon be recommended formally are: (1) For whole body exposure to X- or gamma rays up to three million volts, 0.3 r per week measured in air. (2) For local exposure essentially limited to the *hands only*, 1.5 r per week or 1.5 rep per week in the case of beta rays, in both cases measured at the basal layer of the epidermis, which in general may be assumed to be at a depth of 7 mg/cm² below the surface of the skin.

BIOLOGICAL HAZARDS AND TOXICITY OF RADIOACTIVE ISOTOPES

By AUSTIN M. BRUES

(From the Biology Division, Argonne National Laboratory, Chicago, Illinois)

Clinical use of radioisotopes requires careful consideration of their human toxicity, both from the standpoint of the patient and from that of the individuals who must handle the isotopes before administration and the excreta afterwards. One must take into account not only the possibility of acute overdosage but also the potentially serious end-results of the fixation in the body of isotopes, particularly those of long half-life, which may lead to chronic radioelement poisoning.

Such information as we have regarding radioisotope toxicity is largely indirect. Knowledge of the physical characteristics of the radiation emitted by an isotope, combined with information regarding its metabolic fate, enables us to make approximate calculations of tissue dosage. The pathologic effects of a given tissue dosage have been ascertained only in a few instances, using experimental animals; in other instances pathologic consequences of isotope administration are described but the exact tissue dosage has not been established. Translation of these results to man has been attainable only in the case of radium, where it is known that malignant tumors have occurred in individuals harboring less than one-hundredth the tissue concentration necessary to produce comparable results in experimental animals. Yet the catastrophic consequences of radium absorption in a relatively small number of exposed human subjects have resulted in a wholly justifiable conservatism in our attitude towards human exposure to other radioelements.

Units and Dosage Calculations

In the case of external X or gamma radiation, the roentgen (r) is a well-established unit having an exact physical meaning based on the measurement of ion concentration in air. It has the dimensions of energy per unit of mass, and is approximately 83 ergs per gram of air. From this has been derived the rep (roentgen equivalent physical) or e.r. (equivalent roentgen), describing the amount of alpha or beta radiation causing equivalent energy release. Energy release in soft tissue is approximately (but not exactly) the same as in air on a mass basis.

In the case of alpha radiation, it is known that the biological effectiveness differs from that predictable from the roentgen equivalence. This is due to the increased local density of ionization along the alpha ray track. The consequences of this vary (1) but in the case of toxicity to the higher animals the alpha rays are five to ten times as effective as beta rays yielding equivalent energy.¹ Parker (2) has introduced the unit "rem" to signify equivalence to the roentgen unit in terms of mammalian toxicity.

Computation of tissue dosage is most readily made in the case of a mass of tissue infinitely large with respect to the radiation, and with the isotope distributed homogeneously therein. The dosage is then given by the familiar formula.

$$\text{rep/day} = 60 \times E_m \times C \quad (3)$$

where C = concentration of isotope in $\mu\text{c/g}$ or mc/kg , and E_m is the mean energy of the radiation in million electron volts. The mean energy of beta rays from the common isotopes is not always precisely known, but one-third of the maximum energy serves as a fair approximation.

Where the surface of such a mass of tissue approximates a plane, the dosage at the surface will obviously be one-half of that calculated above; this situation applies to the beta radiation at the surface of a thyroid containing radioiodine. Beta dosage from other sources which may be defined in simple geometry can be calculated only in so far as the beta ray spectrum is clearly defined; the author has attempted to do this in relation to mitotic changes around a point source in tissue (4). Further discussion of tissue dosage will be found in the paper in this issue by Marinelli (5).

Nature of Isotope Toxicity

The toxicity of an isotope given in high dosage may manifest itself as an acute reaction resembling acute radiation sickness. This will occur in its purest form where the tissue radiation is homogeneous throughout the body and approaches the lethal dosage (which, for man, is in the vicinity of 500 r in the case of a single exposure to X-rays). This syndrome (6, 7) is a complicated one depending in part on the destruction of the more radio-sensitive cells (particularly of the blood-forming

¹ It is possible that the weak beta emitter, tritium (H^3) will fall in the same category as the alpha ray emitters, due to density of ionization in the very short path of the beta ray.

organs) and on the release of heparinoid substances into the blood (8). Administration of the short-lived Na^{24} , which equilibrates with the body sodium, may be expected to elicit the syndrome of total-body radiation. It is of interest that the consequences of injecting a pure bone-seeking isotope (as Sr^{90}) in high dosage are quite similar (6), suggesting that bone marrow radiation may be a large component in the acute radiation syndrome. The relative resistance of the mouse to acute radiation anemia following Sr^{90} administration may be attributable to the tendency of this species to develop ectopic myelopoiesis in the spleen (9). P^{32} , because of its tissue distribution, may be expected to approximate the pattern of the acute radiation syndrome.

Subacute radiation reactions occur where external X or gamma radiation is given intermittently or continuously over a long period, or where an isotope of sufficient half-life is retained in high dosage. In its pure form, aplastic anemia is the predominant feature (6). Other effects may occur where the tissue distribution creates a special case. The most carefully studied instance is that of the radioelements which occur in high concentration in the liver. Here, after several weeks, necrosis, cell damage, hyperplasia and fibrosis occur and lead to hepatic insufficiency. Where mice or rats have been injected with radiocerium, the thin edge of the liver, in which radiation dosage is relatively small, may undergo hypertrophy while the bulk of the liver shows necrotic changes.

It is the nature of late or chronic radiation changes which sets the limits of permissible exposure. The chronic insult of a long-lived retained radioelement may result in the gradual development of morbid changes punctuated, after a long latent period, by carcinogenesis. Thus, human radium poisoning may result in bone sarcoma where the retained dose is in the order of one microgram, and sarcoma of the liver has occurred several years after administration of colloidal thorium dioxide (10). Experimental investigation, which has been done on short-lived animals, has yielded comparable results but only with much higher tissue dosage due largely, no doubt, to the shorter period of observation.

It must be remembered that dosage does not have to be given over a long period of time in order to result in malignant changes. This is shown,

in the case of man, by the series of bone sarcomas following X-ray dosage of 1500 r and above (11). It appears clearly that external beta radiation of rats is effective in producing skin and subcutaneous malignant tumors in single, as well as daily, dosage (12). Single dosages of 3,000 rep were effective after a considerable latent period (eight to 12 months). Analogous results have been seen following the feeding, either in single or daily dosages, of radioyttrium (13). While tissue dosage calculations are virtually impossible, it is clear that both single and repeated treatments yield carcinomas of the colon. It seems fair to state that in no instance do we have clear information relating the dosage required for carcinogenesis as a function of time-distribution of treatment; in other words, the recovery factor is unknown (14).

"Tolerance" or Permissible Dose

No doubt the most difficult datum to obtain experimentally is the one most in demand by users of radioisotopes, namely, the amount of radiation exposure which may safely be withstood. We do not, in fact, know whether a threshold exists for such measurable evidences of morbidity as shortening of life or cancer, while in the case of genetic changes it seems likely that no threshold dosage exists below which there is no probability of radiation-induced mutation. In the matter of human permissible exposure, we rely upon two basic "tolerance" values: the permissible retained amount of radium has been set at 0.1 μc , since this is one-tenth of the amount known to have morbid consequences, and the permissible daily X-ray dosage has been taken as 0.1 r daily, for similar reasons. The National Committee on Radiation Protection has recently recommended reducing the latter figure to 0.3 r per week. This action takes into account recent experimental evidence which shows that detectable consequences may follow daily administration of dosages below 1 r daily, and also implies that a dosage of 0.3 r will probably differ little in its freedom from consequences whether administered at once or over an extended period. Indeed, the clinical results of a single dosage of 15 r, measured as the lymphocyte response, are on the threshold of clinical detectability.

Permissible levels for radioisotope exposure must, in general, be derived from the two figures

cited above, in combination with experimental work which may relate toxicities of bone-seeking isotopes to radium (as in the data on Sr^{89} to be discussed later) and with calculations of tissue dosage based on what metabolic information is available. Such calculations are described by Morgan (15) and by Marinelli *et al.* (16). Levels so derived must, of course, be accepted with certain reservations: where they depend upon average figures for absorption, the great variation existing even between "normal" human beings must be taken into consideration, and where they depend upon mean concentration in a critical organ, we must be certain whether the radiation is actually homogeneous throughout the organ. Moreover, we must always be prepared for unexpected experimental results. Thus, plutonium 239 was found to be about 50 times as effective as radium, on the basis of physical comparison, in producing acute radiation disease (17), no doubt due to its very heterogeneous tissue distribution, while Sr^{89} has likewise been relatively more potent than expected in bone tumor production.

Justification for Dosage Exceeding the Permissible

As noted above, the permissible dosage of external radiation is expressed as a daily or weekly amount, applied to the whole body. It can probably safely be assumed that most topographic or histologic parts of the body can receive larger dosages, as in the case of exposure of the hands. Consideration of the methods used in deriving permissible dosages will show the rather general impossibility of deriving data applicable to various parts of the body.

It also seems that a single dose in excess of the daily permissible level can be defended under some circumstances; for example, much routine radiography results in dosages exceeding daily or weekly "tolerance."

With firmly deposited isotopes of long half-life, the daily dose is necessarily continued after deposition. The tendency in this case has been to calculate the amount, giving the maximum permissible level to the critical organ at the height of its concentration there.

The foregoing discussion applies to permissible levels of radiation exposure for normal individuals who receive their exposure industrially or profes-

sionally. Various ranges of exposure may be justifiable, depending upon the nature of the population or upon the reason for administration. They are indicated below, in ascending order of exposure level.

a. The large population: Because of the statistical nature of the genetic sequelae of the lowest dosage levels, it is probably correct to consider that a large population should not be permitted to become exposed to a level of radiation comparable with that which can be justified in special cases. It is likewise possible that tumor development may be slightly enhanced by dosages under "tolerance," but no evidence on this point is available. In the matter of recessive mutations, the size of the exposed population will, of course, determine the probability that, with random mating, the same recessive will occur in both gametes in a later generation. It is, however, probably unnecessary to prescribe levels less than one-hundredth of "permissible," since this level approaches that of the cosmic radiation and the radioactivity normally present in the body.

b. The small, professionally exposed population: It is for such populations that the permissible levels have been applied. Although a possibility of minimal effect, perhaps not detectable, is not ruled out by our present knowledge of the radiobiologic effects of small dosages, it will be recalled that various other industrial and other hazards exist which, again, are merely reduced to the imperceptible level. No low-level hazard has been as carefully studied as that of external ionizing radiation.

c. Clinical investigation and diagnostic procedures: Where such a reason exists for isotope administration, we may fall back on the precedent of diagnostic radiography. Thus, a total dosage of beta and gamma emitters between 1 and 10 rep to the critical tissue may be justified, if not repeated, in the case of certain isotopes of short half-life whose metabolic fate is well understood, *e.g.*, Na^{24} , K^{42} , I^{131} , and possibly P^{32} . For the present, the bone-seeking isotopes in general, as well as those whose metabolic fate is in doubt (C^{14} in particular), should not be used in this category. Isotopes in a borderline class include Fe^{55} , Fe^{59} , Ca^{45} , and the long-lived isotopes Na^{22} and Cl^{36} ; with these, somewhat more caution is indicated than with the shortest-lived radioelements. As examples of actual practice, Na^{22} has been used in

normal subjects (18) in such a way as to yield somewhat less than 1 rep total integrated dosage ($90 \mu\text{c}$ in man); Fe^{55} and Fe^{59} have been used in normal blood donors (19) in such dosage as to yield a maximum of 0.1 rep per week in blood. P^{32} has been given to human subjects to establish its turnover in tumors, including operable tumors. In one recent study, $1 \mu\text{c}$ per pound body weight was used and it was estimated that the total-body irradiation would not exceed 1.5 r (20) (integrated over time and over the body volume). The attitude toward I^{131} , on the other hand, has been somewhat more liberal, presumably because this isotope is virtually confined to the thyroid. Thus, for diagnostic purposes, 20 rep per day to a total dose of 230 rep has been given as calculated thyroid dosage (21).

It is clear that improvements in technique of measurement of isotopic radiation will greatly benefit work in this area, since many studies will be brought within the limits of reasonably safe operation. As it is now possible actually to estimate naturally occurring C^{14} within 5–10 per cent (22), this is an important direction in which clinical isotope work can find new opportunities.

d. Treatment of disease where other therapy is available: In this range, dosage must necessarily far exceed that required to produce visible changes in the organism, since changes are being sought. The principle of calculated risk is therefore paramount, as indeed it is in all clinical therapy and especially in surgery. There are, however, certain pervading differences. In the first place, the risks in surgical and pharmacologic therapy are mainly immediate, easily observed and soon calculable; whereas in isotope therapy the most important risks may be disclosed by the passage of a considerable amount of time, as shown by the results of radium absorption and by the late consequences of the use of colloidal thorium dioxide (even where used for diagnostic purposes) (10). Secondly, there are certain unknown factors which make calculation of risk, to an order of magnitude, impossible. We do not know the relation between latent period before carcinogenesis and the lifespan of a species, or the relations between the probability of tumor development and the volume or type of tissue irradiated or the time distribution of radiation. On a more basic level, we understand next to nothing about the mechanism of radiation

carcinogenesis or the meaning of the shortening of life after total-body irradiation.

In two instances, there is a fairly large backlog of experience in therapy of disease with radioisotopes. These are the treatment of benign thyroid disease (especially exophthalmic goiter) with radioiodine and of leukemia and polycythemia vera with P^{32} . Therapy of polycythemia vera has yielded results similar to those of X-ray given to the whole body, and is logical inasmuch as bone marrow receives a larger dosage than the integrated total-body dose. One mc administered to a 60 kg man yields an integrated total body dosage of about 15 rep, neglecting loss by excretion, at a rate less than 1 rep per day; the bone marrow, spleen, and lymph nodes may receive two to three times as much. Thus, dosages of 1–5 mc correspond to total-body X-ray treatment ranging between 15 and 75 r, or somewhat more to bone marrow. The time distribution of the radiation probably makes it somewhat less toxic (and less effective) than X-ray given according to usual patterns of treatment.

Although dosages of this sort are in accord with regular practice in radiation therapy, it is possible that deleterious results may occur. This has been suggested by Hall and Watkins (23) in whose series of P^{32} -treated cases a number of acute leukemias arose. Because of the frequency of chronic leukemias and leukemoid states arising in the course of the disease, it is difficult to evaluate these results until further information is available. Our own observations (24) show that P^{32} is leukemogenic to mice, but that the effect is not strikingly different from that of total-body X-ray in equivalent dosage.

In treatment of thyrotoxicosis, I^{131} has been used in relatively high thyroid dosage by a number of clinical groups. This question has been discussed recently by Nickson (25). Dosage of 200 or more microcuries per gram of thyroid are frequently used, with a resultant total radiation dose in excess of 10,000 rep. The actual dose has been estimated to be as much as 26,000 rep with $200 \mu\text{c/g}$ (26), but is difficult to estimate, since it depends on the rate of loss of iodine from the treated gland. If the dose to the tissues immediately surrounding the thyroid is one-half to one-fourth of this, it appears that the adjacent connective tissue receives thousands of rep. This is

in the range of dosage by X-ray which has resulted in bone tumors in man (11), and it will be recalled that 3,000 rep of external beta radiation to rats from P^{32} has resulted not only in epitheliomas, but in subcutaneous sarcomas as well (12). It is, therefore, within the bounds of possibility that carcinogenic effects may occur from dosages as used in the treatment of thyrotoxicosis, although it is encouraging to note that no reports of such sequelae have appeared after several years' clinical experience.

An intermediate group of diseases exists, namely the leukemias and allied disorders, in which certain isotopes (Na^{24} [27], P^{32} , As^{76} [28]) are used in place of total-body radiation for similar palliative purposes. In all of these instances the net effect of the radiation is either equivalent to that of total-body X-ray, or it is distributed in favor of bone marrow and blood-forming organs. Since the peripheral blood picture gives indication both of toxicity and of therapeutic effectiveness, it is useful in monitoring treatment. It should be recalled that the same general remark applies to the use of radiomimetic chemicals, *e.g.*, the alkylamines.

e. Treatment of hopeless malignant disease:

Here it would seem justifiable to use whatever means offer some chance of palliation or cure, or of gaining information to that end where this can be done without detriment to the patient. In the case of metastasized malignant disease of the thyroid, it would seem proper to treat every patient with I^{131} in order to determine the response. Although certain histologic types have been found not to concentrate iodine (29), it has been shown that the capacity to store this element may be enhanced by thyroidectomy or administration of thyrotrophic hormone. Dosages have been large; in one case (29) where the dose to the normal thyroid is stated, the gland should have received 36,000 rep on the first day (assuming immediate uptake) to an ideal total (barring subsequent loss) of 430,000 rep. Treatment in this order of magnitude has been possible only in the treatment of thyroid disease. Dosage to metastases in this case was $\frac{1}{70}$ of that to thyroid (*viz.*, about 6,000 rep).

In breaking new ground, the long-lived isotopes will be tested. The possibilities of C^{14} and H^3 in organic compounds are manifold, and es-

entially no exploration has been done at the present time. The use of Sr^{89} has also been suggested. Because of the known chronic toxicity of the latter and the potential hazard in the use of other long-lived isotopes, it will be essential that cases be selected on the basis of inoperability. It may be suggested that all patients be chosen (1) as a result of biopsy from a metastatic lesion, or a primary lesion deemed inoperable or (2) after consultation with a specialist in this particular field. There are few physicians who have not, on some occasion, misjudged the prognosis of a clinical situation resembling inoperable cancer. It has also been advocated that such treatment be given only after exhaustive experimental study. This is desirable in cases where the toxicity of the isotope or the isotopic compound is unknown, but it should be recalled that the variety of human cancer is greater than that easily available in laboratory animals, so that the appropriateness of the treatment for a given tumor type may need to be evaluated by tracer studies in patients, or (for C^{14}) by use of the stable C^{13} .

As mentioned before, the short-lived isotopes, and especially those yielding hematologic changes as readily as total-body X-ray, may be used with the same precautions as are used with external radiation or chemotherapeutic agents, as far as the patient is concerned. It will be seen that the short-lived isotopes may be intense radiation sources and require special care during preparation and administration.

Toxicity of Bone-seeking Elements

In order to gain some quantitative expression of the carcinogenic action of radioactive substances which might have general meaning, large series of animal experiments were set up in this laboratory using Sr^{89} in rats and mice. It was hoped thereby to observe the pattern of bone tumor induction (as pilot experiments had shown [30]) by a very potent carcinogen the effectiveness of which was due to beta irradiation of bone. A preliminary discussion of these experiments was included in our earlier report (14). The data are still incomplete pending histologic verification of the gross pathologic findings. One of the strains of mice used has shown an unexpectedly high incidence of bone lesions of various sorts, including benign tumors.

Experimental: The mice used in these experiments were females of the Carworth CF-1 strain and male and female ABC hybrid mice obtained from the Roscoe B. Jackson Memorial Laboratory. These mice were chosen because of their ready availability in large numbers at the time the experiments were begun (1945-6) and because they had no specialized tumor characteristics which might obscure the study of the general tumor hazard, except for a high incidence of spontaneous lymphoma and lymphatic leukemia. A few high-lymphoma C58 strain mice obtained through the kindness of Dr. E. C. MacDowell were also used.

The animals were housed in an air-conditioned animal farm to permit regulation of temperature (*circa* 23° C.). Triethylene glycol vapor was used to minimize the possibility of air-borne cross-infection. The mice were received in lots of over 600, equally divided among the three permutations of strain and sex. One-fifth of the total experiment, including aliquots of the dose levels used, was set up upon receipt of each shipment, and injected at $42 \pm$ seven days of age. Each component group of animals remained caged together throughout the experiment. It was found that certain cages of animals suffered from infectious disease, but cross-infections to nearby cages were rare. The commonest infectious diseases were pneumonia (with intracellular pleuropneumonia-like organisms) and intestinal or generalized infections due to *Salmonella* and *Pseudomonas*.

Since the acute lethal dose (30-day LD_{50}) for Sr^{90} in mice was found to be 8 $\mu\text{c/g}$ body weight, the highest single dosage used was 5 $\mu\text{c/g}$, and lower dosages were employed, differing by factors of approximately 2, down to 0.05 $\mu\text{c/g}$. A parallel series was given monthly dosage with one-fifth of the above amounts in such a way as to bring the dosage to the same level each month. Increasing numbers of mice were used in the lower dose levels in order to maintain statistical significance, if possible, where tumor incidence would be less; the design of the experiment is shown in Table I.

All mice were observed daily; those showing evidence of serious disease were followed with particular care and sacrificed when *in extremis*. By adequate clinical observation it became possible to salvage over 95 per cent of the fatally ill animals before death. Complete autopsy (except for the central nervous system) was performed,

sections were taken where considered necessary, and the carcasses preserved in 4 per cent formaldehyde. Roentgenograms were made in all cases at or after death.

RESULTS

Survival was definitely shortened at the higher dosage levels, as might be expected. This is illustrated graphically in Figure 1, in which a separate family of curves is shown for survival of the groups injected singly and monthly. Because of the obvious similarity among the types of mice used with reference to longevity and bone tumor genesis, they have all been pooled in assembling the data in preliminary form. The last survivor in the ABC female control group died 895 days after the beginning of the experiment (about 937 days of age) and the last CF-1 female died after 876 days (about 918 days of age). The ABC male group in the experiment was shorter-lived, falling (for the last 5 per cent of survivors) about 100 days behind the females of the same strain.

Even at the highest dosages, no "acute" radiation deaths occurred during the first month. The earlier mortality among these mice is not ascribable to any single cause. In addition to bone tumors, aplastic anemia and myeloid metaplasia (the latter probably a compensatory response) (9) were commonly observed at autopsy, and graying of hair, which is a frequent subacute sequela of total-body radiation, was noticeable. Of the mice receiving 5 $\mu\text{c/g}$ and surviving 200 days, 35 per cent died before 250 days without bone tumors and an additional 14 per cent, with bone tumors; of the controls, 5 per cent of the 200-day survivors died in the same period.

Incidences of tumors, other than those arising in or near bone, have failed to undergo changes attributable to the treatment. A small apparent increase in lymphomas in the heavily-treated CF-1 and ABC mice has been shown to lack statistical significance.

Tumors in or near bone were of several types; osteogenic sarcomas predominated, but other malignant tumors of mesenchymal and endothelial origin have been observed, and for statistical purposes have been included with those of osteoid origin. Multiple primary tumors occurred with an entirely random frequency, their incidences conforming well to the Poisson distribution. Thus, multiple tumors are more frequently seen as the

TABLE I
Design of large mouse experiment with Sr^{90}

Dose	Single injection	Monthly injections	Dose
$\mu\text{c/g}$	number of mice	number of mice	$\mu\text{c/g}$
5	45	45	1
2.5	60	60	0.5

FIG. 1. CHART SHOWING SURVIVAL OF MICE GIVEN VARIOUS DOSES OF Sr^{90}

Open circles represent single injections; closed circles, dose given monthly.

dosage increases. It may be postulated from this that one tumor, already present, does not suppress or stimulate the genesis of others.

A very striking feature of treatment with the higher dosages is the sharpness of the latent period, at the end of which tumors appear rapidly. It seems clear that the latent period cannot be explained (where a single dose is given) by the time required for a tumor to develop from a single cell if the cellular growth rate is constant, unless the tumor is formed some time after the greater part of the radiation has been delivered. As stated earlier, the prolonged latent period is characteristic of radiation carcinogenesis.

In attempting to understand quantitatively the process of carcinogenesis, the data have been plotted in a variety of ways. The simplest function was seen where the tumor morbidity rate was plotted directly against time, in mice given continuing dosage. These data are shown in Figure 2. The ordinates represent the probability that a mouse in a given dosage group will develop a tumor (or possess a tumor at a certain early stage of development) on a given day, and this figure is obtained by calculating, for 40-day overlapping time intervals, the proportion of mice which will die with bone tumors within 40 days. This figure, divided by 40, gives the daily expectancy, or morbidity rate, P_t . The time scale is adjusted to the beginning of the 40-day period

before death, and therefore represents tumors at about the time they are first visible, or somewhat before that time.

It will be seen that this function gives essentially a straight line cutting the horizontal axis at the "latent time"; the slope of the line being proportional to dose, and the latent period varying gradually with dose, perhaps as a logarithmic function. The straight lines have been drawn in accordance with an empirical formula:

$$P_t = Kd (t - t_e)$$

where $(t - t_e)$ represents time after the end of the latent period, and d is proportional to the dose, where the monthly dosage is expressed in $\mu\text{c/g}$, and time in days, and K is taken as 1.4×10^{-4} . The latent period may appear, on inspection, to vary with the logarithm of the dosage, or with an inverse root of the dosage (approximately the square root). The latter function is indicated, quite qualitatively, as a broken line in Figure 1, and shows graphically the impossibility of producing tumors with low dosages in short-lived animals.

It is significant that the accumulated number of tumors at any time after the end of the latent period is a function of $t \times P_t$, and hence of the square of time. In this way, it is seen that the low dosage required to induce radium tumors in man is consistent with the longer period in which tumors

FIG. 2. DAILY PROBABILITY OF BONE TUMOR DEVELOPMENT (P_t) AS A FUNCTION OF TIME AFTER BEGINNING OF MONTHLY INJECTIONS

Figures beside the curves indicate dosages in $\mu\text{c/g}$.

may develop than in experimental animals. One semiquantitative expression of this has been stated (14). The data shown in Figure 2 may be interpreted in this way: that each quantity of absorbed radiation confers on the tissue absorbing it a probability of tumor formation which is *without limit in time*, once the latent period is passed; thus the daily tumor morbidity will constantly increase as long as further irradiation occurs.

I am indebted to Dr. R. D. Evans (31) for pointing out that the data shown here are also consistent with a Gaussian distribution of tumors around an optimal time after treatment, where the parameters are specified functions of dose. It would be virtually impossible to distinguish between these two expressions with such experimental data as can be obtained by the techniques used here.

When a single injection of Sr^{89} is given, we

FIG. 3. DAILY PROBABILITY OF TUMOR DEVELOPMENT AS A FUNCTION OF TIME AFTER A SINGLE INJECTION OF Sr^{89} , AS IN FIGURE 2

might expect to see a somewhat simpler function. That this is not the case appears from Figure 3. Here we again see a sharply defined latent period, followed by an increase in tumor morbidity. These data also indicate that the subsequent morbidity is, within the limitations imposed by survival, relatively without limit in time after the latent period is passed.

Further data regarding the pattern of tumor formation in mice and in other species will be published in the future, when the pathologic data are complete. The preliminary results suggest that (1) in rats and mice, the tumor incidence following radium administration gives a ratio of effectiveness of radium: strontium⁸⁹ of about 10:1 on a millicurie basis; and (2) that the response to bone-seeking radioelements as regards latent period and tumor incidence per animal is comparable as between rats, mice, and rabbits, and is certainly no greater in dogs.

DISCUSSION

Such data as have been obtained from a variety of sources still fail to answer a number of questions which must be understood before it will be possible to make direct application of experimental data to man, especially in the tolerance range.

In the first place, the question whether there is a true threshold for carcinogenic effects appears to be entirely unanswered. The scantiness of human data on the one hand, and the short life-span of animals on the other, makes it impossible to say what effects might be seen in a large human population after a long period of time. The human experience has been reviewed by Evans (32) in some detail, and the author concludes that total dosages of 1000 to 10,000 rep for alpha radiation have been required to induce an incidence of 10 per cent tumors after 15 years. The X-ray data previously cited (11) and the bulk of animal data involving absorbed isotopes leave the impression that the lowest amount of X-radiation or beta radiation which has been clearly shown responsible for carcinogenesis (excepting mouse lymphoma) may be of the same order. It cannot be said whether underlying visible tissue changes are necessary to radiation carcinogenesis, or whether it is a statistical event that may (with a very low probability) occur whenever a cell lies in the path of ionization.

Secondly, the relation between life-span of a

given species and the latent period before tumor formation requires study. In the matter of chemical carcinogenesis, it appears that the period of latency for the dog and man is longer than in the rodents. We are not aware that such a relationship has clearly been shown for radiation-induced neoplasia under controlled conditions.

Finally, the concept of the origin of malignant disease (whether a stray statistical event taking place in a single cell, or a systemic change) has considerable bearing on the relation between human and experimental results. The former concept is consistent with the observed distribution of tumors within a group of animals, since multiple primary bone tumors do not appear to occur with undue frequency. Assuming that cancer is a disease arising in a single cell, and that all the cells of a tissue are more or less equally susceptible to the change, it can be seen that even under a strong stimulus the carcinogenic event has a numerical rarity comparable to the incidence of genetic mutations. In that event, man might be expected by virtue of mass and cell number to have a susceptibility to tumor formation on the order of 1,000 times that of the mouse. It will be obvious that this is not the case, and that if it were, the survival of the larger species would be impossible. Thus the extrapolation of the carcinogenic effects of radiation from rodents to man involves unknown variables in several parameters, and poses some of the basic problems in cancer biology.

SUMMARY

The effects of large dosages of radioisotopes resemble to a marked extent those of total-body radiation, with modifications dependent on tissue distribution. Permissible exposure levels are determined by the late or chronic radiation changes, of which malignant changes have quite properly attracted major attention.

There is no evidence to indicate that radiation dosages to tissue corresponding to established "permissible" external dosages (0.3 — 0.6 rep/week) will result in an increased incidence of malignant disease detectable in a population of moderate size. In making such calculations, it is necessary to estimate maximum local tissue dosage, rather than the mean value for an organ or structure, and to make use of factors recognizing the greater effectiveness of ionization in areas

where it is dense (*e.g.*, alpha-particle ionization).

The suggestion is made that a more conservative figure is desirable where a large population may be affected, and the basis for using larger dosages in clinical investigation, diagnosis, and therapy is discussed.

Bone tumor induction by Sr^{90} has been studied extensively in mice. The data are consistent with the view that each given quantity of radiation to bone confers a given probability of bone tumor formation which may occur at any time following a "latent period." The latent period increases gradually with the dosage. It is not known at present whether a threshold exists for such effects.

ACKNOWLEDGMENT

The experimental work was done in collaboration with Drs. Hermann Lisco and Miriam Finkel, to whom the author is also indebted for valuable suggestions in the preparation of this paper.

EQUATIONS FOR TRACER EXPERIMENTS

By A. K. SOLOMON

(From the Biophysical Laboratory, Harvard Medical School, Boston)

The use of isotopes makes possible quantitative measurements of many biochemical and physiological processes, hitherto secure from such detailed observation. Perhaps the most frequent use of this tool is in the observations of physiology that are concerned with the transfer of fluid from one portion of the body to another, and in the biochemical observations of the formation of one compound from another. It is the purpose of this paper to present in detail some of the mathematical equations that govern such flow and synthesis, and to show incidentally that many of these equations are common to the fields of physics, and chemistry, as well as to the biological disciplines to which they will be applied here. A series of case studies will be presented, including, as examples, the formation of cholesterol from deuterium-marked body water, the uptake of phosphorus by the red blood cell and the flow of sodium out of the plasma into cerebrospinal fluid.

Mathematical analysis of this kind is certainly not novel; indeed, Burton (1) reports that Harcourt and Esson (2) concerned themselves with similar studies in 1866 when chemical kinetics was just beginning. In another connection, Rutherford, Chadwick and Ellis (3) have expressed some equations governing the familial relationship between radioactive parent elements and their daughters; they report that Bateman (4) as early as 1910 developed a theory which covers the general case of radioactive decay and recovery. The mathematics apply so generally that any survey of the literature must necessarily be incomplete.

1. Basic assumptions

The basic assumption that underlies all the equations to be developed is that the tracer element follows its unlabeled isotope faithfully in all biological reactions. Qualitatively there is good agreement on this point; quantitatively, evidence is gradually accruing that the rates of reaction are influenced by the isotopic composition of the reacting molecules. However, no

allowance has been made for this in the cases to be discussed. Implicit in this primary assumption is the condition that the injection of the tracer element shall not disturb, in any important fashion, the normal metabolic behavior of the system. As a consequence of this initial assumption, the equations to be derived apply to unlabeled systems also; the tracer provides the method of measurement.

The second basic assumption is that in systems of constant volume the rate of flow of isotope out of a compartment is proportional to the amount of labeled isotope present in the compartment. This reduces to the assumption that rate is proportional to *concentration*, given constant volume. The difference is purely formal and can be taken up by suitable adjustments of the constants involved. Thus, the investigator has his choice of expressing the activity as, say, counts per milliliter, or counts per milliliter times the volume of the compartment in milliliters. The equations that follow have been based on amount. In systems in which the volume is not constant, other assumptions are made.

A third basic assumption is that of uniform distribution throughout the compartments. There are many physiological conditions in which this assumption is invalid, as when the time of mixing is long compared to the reaction rate, or when the viscosity of the fluid in the compartment is high. In many cases, the experimental conditions can be adjusted in order to make these factors unimportant; if not, suitable corrections must be applied.

2. Symbols

- P = total amount of labeled material in compartment A.
- P_0 = P at time 0.
- t = time.
- k_{ab} = coefficient of transfer from compartment A to compartment B.
- p = concentration of labeled material in compartment A.

- v_p = volume of compartment A.
 Q = total amount of labeled material in compartment B.
 k_{ba} = coefficient of transfer from compartment B to compartment A.
 q = concentration of labeled material in compartment B.
 v_q = volume of compartment B.
 k_{ao} = coefficient of transfer from compartment A to outside.
 etc.

3. Case 1—Simple decay

The decay of a radioactive isotope can be described by an equation which states that the rate of loss of isotope depends upon the amount of isotope remaining. This is perhaps the most common example of simple decay. In chemistry, monomolecular reactions are governed by a similar equation, since the rate of reaction is dependent on the amount of reactant remaining (though not necessarily independent of concentration). Margenau and Murphy (5) point out that the rate of growth of bacterial cultures in an unlimited nutrient medium is dependent on the number of bacteria present; thus the equation is similar to that for radioactive decay, though the sign, of course, is different.

$$1-1 \quad \frac{dP}{dt} = -k_{so}P$$

$$1-2 \quad P = P_0 e^{-k_{so}t}$$

$$1-3 \quad \ln P = \ln P_0 - k_{so}t$$

$$1-4 \quad t_{\frac{1}{2}} = 0.693/k_{so}$$

Figure 1 shows the decay of radioactive phosphorus (P^{32}). The amount of this material remaining, P (expressed as relative counts/minute in a unit mass of sample) is plotted on a logarithmic scale against t . The slope of this straight line gives k_{so} , from which the half-life, $t_{\frac{1}{2}}$, may be derived by equation 1-4. In this case, $t_{\frac{1}{2}}$ measures the time required for half the material to disintegrate.

4. Case 2—Uptake from a constant source

This case arises most frequently in stable isotope experiments in which the body fluids are brought to a constant deuterium level, and the uptake of deuterium in various compounds is

examined. The basic assumption is that the isotopic content of the circulating fluids remains constant. This includes the implicit assumption that the return of material to the circulating fluids from the compartment examined is unimportant.

This example of Case 2 is shown diagrammatically in Figure 2. Here compartment A represents the body fluids, and P represents the total amount of deuterium in the fluids. The concentration, p , is given by the atom per cent deuterium in the body fluids. Compartment B represents the cholesterol; Q is the total amount of deuterium in the cholesterol, and q is the concentration of deuterium given by atom per cent deuterium in the cholesterol (usually referred to atom per cent D in the body fluid as 100%).

Another common example of this case is the formation of radioactive isotopes in nuclear reactors. The basic assumption in this case may be restated: the flux of neutrons must remain constant, and be unaffected by the products formed in the material being irradiated.

$$2-1 \quad \frac{dQ}{dt} = k_{ab}P - k_{bo}Q, \quad P = P_0 = \text{const.}$$

$$2-2 \quad Q = \frac{k_{ab}}{k_{bo}} P_0 (1 - e^{-k_{bo}t})$$

$$2-3 \quad Q_{\infty} = \frac{k_{ab}}{k_{bo}} P_0, \quad t = \infty$$

$$2-4 \quad \ln(1 - Q/Q_{\infty}) = -k_{bo}t$$

$$2-5 \quad t_{\frac{1}{2}} = 0.693/k_{bo}$$

These equations differ materially from those of simple decay. For one thing the half-life is dependent upon the rate of decay of the material in compartment B, not on the rate of its synthesis, unless an equilibrium obtains, in which case the two rates are equal. The dependence of half-life upon decay may be illustrated by considering the formation of isotopes in reactors. For a given rate of decay, that is, a given half-life, the *amount* of material formed depends directly on the intensity of the neutron flux. The *time* it takes to achieve the maximum formation of radioactive material is dependent on the half-life and independent of the neutron flux. That is, more radioactive material can be formed by an increase in neutron flux, but the time it takes to reach the new maximum value is independent of this increase in neutron flux.

FIG. 1. CASE 1: RADIOACTIVE DECAY OF P^{32}

Relative counts/min. in a unit mass of sample is plotted on a logarithmic scale against time.

In order to determine whether the equation 2-1 holds for conditions in which the volume is not constant, the equation 2-1 has been fitted to experimental results on the uptake of deuterium by maternal and fetal cholesterol reported by Goldwater and Stetten (6). Pregnant rats put on a heavy water regimen in the 18th day of term were sacrificed at quarter-day intervals from the 18th to the 19th day, and at half-day intervals from the 19th to the 20th day. One control was kept on the heavy water regimen for the total 20-day term in order to determine the maximum uptake of deuterium in the fetal cho-

lesterol, and the maternal cholesterol, both liver and carcass. In the two-day period between the 18th and the 20th day, the weight per fetus varied between 2 and 5.2 grams. The tissue content of cholesterol in all three cases showed a slight increase. Thus, the amount of cholesterol, the volume as it were, of compartment B is certainly not constant.

The weight increase in the maternal rat will show whether constant isotope concentration in the body fluids is equivalent to a constant amount of deuterium in the fluids. If one ascribes the weight increase to increase in fetal

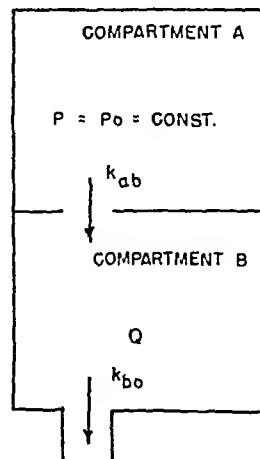

FIG. 2. CASE 2: UPTAKE OF DEUTERIUM BY CHOLESTEROL IN THE MATERNAL RAT AND FETUS

The function $(1 - q/q_\infty)$ is plotted on a log scale against time. The slope of the curve determines the transfer coefficient k_{bo} .

weight alone, Goldwater and Stetten's figures show that the average increase in maternal rat weight in the two-day period is about 11%. This is small compared to the other changes in the system; hence, we will assume that both concentration and amount of deuterium in the body fluids remain constant.

If the assumptions in equation 2-1 are correct, the function derived in equation 2-4 should fall on a straight line when plotted against time. Since it does not, a different assumption must be made. We may test the assumption that the rate of change of the *amount* of labeled cholesterol is proportional to the *concentration* of deuterium in the body fluids, and the *concentration* of deuterium in the cholesterol. Stated analytically, this becomes:

$$2-6 \quad \frac{dQ}{dt} = k_{ab}P - k_{ba}Q$$

If one assumes that the change in cholesterol content in the fetus varies linearly with time, an assumption supported by the data, this equation can be solved. In this case, too, the equation is seen to fail in describing the data. However, when one assumes that the rate of change of *concentration* of cholesterol is proportional to the *concentration* of deuterium in the body fluids and the *concentration* of deuterium in the cholesterol the equation fits the data. In this case the equation becomes

$$2-7 \quad \frac{dq}{dt} = k_{ab}P - k_{ba}Q$$

and 2-4 reduces to

$$2-8 \quad \ln(1 - q/q_{\infty}) = -k_{ba}t$$

The calculations are given in Table I, and the function is plotted in Figure 2. It will be seen that all three cases fit the equation nicely, even though the volume in compartment B is greatly changed during the course of the experiment. Many chemical systems can be postulated that can be described analytically by equation 2-7.

5. Case 3—Closed two-compartment system

The equilibration of red blood cells with K^{42} -marked plasma is used as an example of this case. The basic assumption is that the total amount of labeled material in the system remains constant. In Figure 3 this case is shown diagrammatically. Compartment A represents the

plasma containing an amount P of K^{42} , and compartment B represents the erythrocytes containing an amount Q of K^{42} .

Since Cohn and Cohn (7) investigated the permeability of the red corpuscles of the dog to sodium ions, many experiments have been carried out on cellular permeability. Sheppard (8) has recently reviewed these experiments and reported some additional results of his own. The equations he derives, specific examples from a previously published general treatment (9), correspond with those to be derived below.

$$3-1 \quad P + Q = P_0 = \text{const.}$$

$$3-2 \quad \frac{dP}{dt} = -k_{ab}P + k_{ba}Q$$

$$3-3 \quad \frac{dQ}{dt} = k_{ab}P - k_{ba}Q$$

$$3-4 \quad Q = \frac{k_{ab}}{k_{ab} + k_{ba}} P_0 [1 - e^{-(k_{ab} + k_{ba})t}]$$

$$3-5 \quad Q_{\text{equil}} = \frac{k_{ab}}{k_{ba}} P_{\text{equil}}$$

$$3-6 \quad Q_{\infty} = \frac{k_{ab}P_0}{k_{ab} + k_{ba}}$$

$$3-7 \quad \ln(1 - Q/Q_{\infty}) = -(k_{ab} + k_{ba})t$$

$$3-8 \quad t_{1/2} = 0.693/(k_{ab} + k_{ba})$$

$$3-9 \quad P = \frac{k_{ba}P_0}{k_{ab} + k_{ba}} \left[1 + \frac{k_{ab}}{k_{ba}} e^{-(k_{ab} + k_{ba})t} \right]$$

$$3-10 \quad P_{\infty} = \frac{k_{ba}P_0}{k_{ab} + k_{ba}}$$

$$3-11 \quad \ln(P/P_{\infty} - 1) = -(k_{ab} + k_{ba})t - \ln \frac{k_{ba}}{k_{ab}}$$

The example chosen to illustrate this case has been taken from some unpublished work of Raker, Taylor and Weller (10) on the uptake of K^{42} by human erythrocytes in a dilute solution of K^{42} -marked plasma. Figure 3 shows the function $(P/P_{\infty} - 1)$ plotted on a logarithmic scale against time. The constants describing the system may be determined as shown in equation 3-11 from the slope and intercept of this line. The calculations have taken account of a slight swelling of the cells towards the end of the experiment, as shown by a 10% increase in the hematocrit. This change in volume of compartment B is so small, however, that it does not affect the fit of the equation. The function $(P/P_{\infty} - 1)$ in equation 3-11 is plotted on a logarithmic scale against time in Figure 3. A curve drawn on the assumption that the flow of

* D₂₀ represents the D of the various fractions for the rat which was fed D₂O for the total 20-day period.

K⁴² is determined by its *concentration* in plasma and cells fits the data equally well, and is probably preferable on theoretical grounds.

The symmetry of this system is very interesting. The observations of the time course can be made on either plasma or cells, provided that

FIG. 3. CASE 3: UPTAKE OF K⁴² BY RED BLOOD CELLS FROM PLASMA

The function $P/P_{\infty} - 1$ is plotted on a logarithmic scale against time. From the slope and intercept of this curve the transfer coefficients k_{ba} and k_{ab} may be determined.

the equilibrium amounts in both compartments be determined. Indeed, it is theoretically possible, though not experimentally desirable, to characterize this system exactly by only three measurements: the amount of isotope in either component at any time t , prior to equilibrium, and the equilibrium amounts.

6. Case 4—Diffusion or flow out of a compartment

An example of flow out of a compartment is the escape of sodium from the blood stream following a single intravenous injection. Merrell, Gellhorn and Flexner (11) have derived equations which describe this process in the guinea pig. In the case of the guinea pig, the process can be described by a simple exponential similar to, but not identical with, that given in Case 3, in which compartment A is the plasma and P is the amount of tracer sodium in the plasma. Merrell *et al.* assume that the process of sodium movement is one of diffusion, that is, that the coefficient of transfer into the plasma equals the coefficient of transfer out when the equation is expressed in terms of concentration of sodium in the various compartments. Apparently, it is assumed implicitly that there is no sodium excretion during the course of the experiments.

In the dog (Gellhorn, Merrell, and Rankin [12]) and in man (Flexner, Cowie, and Vosburgh [13] and Burch, Reaser, and Cronvich [14]), the process is described by at least two separate rates. A two-rate system (neglecting return from extra-cellular fluid to plasma) implies the presence of a split compartment in the extra-cellular fluid, rather than a compartment with two leaks of different size. Two leaks of different size are equal to one leak of larger size, and can be described by a single transfer coefficient. However, as Gellhorn *et al.* point out (12), the situation is far different when the return of Na^{24} to the plasma is taken into account. Assume that the Na^{24} escapes from the plasma into two separate external compartments as shown diagrammatically in Figure 4, entering one quickly and the other slowly. The return from these two compartments to the plasma must be characterized by two different rates, since the amount of tracer in compartment B is different from the amount in compartment C.

Thus, the flow of Na^{24} from the plasma will be described by an equation containing at least two exponentials. It is not assumed that the compartments B and C exist as such in the body, but rather that one, say B, represents the average of a number of areas to which the sodium is transferred quickly, and the other, C, the average of a number of areas to which the sodium is transferred more slowly.

In the treatment that follows, three basic assumptions will be made: first, that the volume of the compartments remains constant; and second, that there is no excretion of Na^{24} during the period of observation. For simplification, we will also assume that the coefficient of transfer across the membrane separating the compartments is the same in both directions. That is,

$$4-1 \quad k_{ab} = k_{ba} = k_1; \quad k_{ac} = k_{ca} = k_2$$

The equations that follow are similar to those derived by Gellhorn *et al.*, and the reader is referred to Appendix 1 of reference 12 for the derivation.

$$4-2 \quad \frac{dP}{dt} = -k_1P + k_1Q - k_2P + k_2R$$

$$4-3 \quad \frac{dQ}{dt} = k_1P - k_1Q$$

$$4-4 \quad \frac{dR}{dt} = k_2P - k_2R$$

$$4-5 \quad P + Q + R = P_0$$

$$4-6 \quad \frac{d^2P}{dt^2} = -2(k_1 + k_2) \frac{dP}{dt} - 3k_2k_1P + k_2k_1P_0$$

$$4-7 \quad P = a_1e^{-b_1t} + a_2e^{-b_2t} + \frac{1}{3}P_0$$

where

$$a_1 = \frac{1}{3}P_0 + \frac{1}{6}P_0 \frac{(k_1 + k_2)}{\sqrt{k_1^2 - k_1k_2 + k_2^2}}$$

$$a_2 = \frac{1}{3}P_0 - \frac{1}{6}P_0 \frac{(k_1 + k_2)}{\sqrt{k_1^2 - k_1k_2 + k_2^2}}$$

$$b_1 = (k_1 + k_2) + \sqrt{k_1^2 - k_1k_2 + k_2^2}$$

$$b_2 = (k_1 + k_2) - \sqrt{k_1^2 - k_1k_2 + k_2^2}$$

$$4-8 \quad \text{At equilibrium,}$$

$$P = Q = R = \frac{1}{3}P_0$$

In the course of studies now in progress to determine the uptake of Na^{24} by cerebrospinal fluid, Sweet, Solomon, and Selverstone (15) have examined the diffusion of this isotope from human plasma. The results have been plotted in Figure 4, and analyzed on the basis of the equation 4-7. For the purpose of this example, a smooth curve drawn through the experimental

FIG. 4. CASE 4: DISAPPEARANCE OF Na^{24} FROM PLASMA IN MAN

Counts/min. in 0.1 ml in the plasma is plotted on a logarithmic scale against time. The transfer coefficients may be determined from the slopes and intercepts of the first and second rates, and the value of the constant term.

points has been used; the full data will be published elsewhere. In Figure 4, the radioactivity has been expressed as counts per minute in 0.1 ml, plotted on a logarithmic scale against time; since constant volume is assumed, this expression is a valid index of the total amount of radioactivity, P. In order to analyze a curve plotted in this way into its components, the constant term is first subtracted graphically from the curve. The difference between these two curves, shown in Figure 4 as the crosses, is then plotted, and the straight line is drawn which best fits these points. That straight line gives

the second rate and has the slope $-b_2$. It, in turn, is subtracted from the points represented by the crosses that do not fall on the line at the beginning of the period of measurement. Thus, the first rate, given by the circles on Figure 4, is obtained. The method of analyzing experimental curves by a sum of exponentials with constant coefficients is so powerful, and the number of adjustable constants so large, that great care must be taken in interpreting such curves physiologically.

Accepting this curve as a formal description of the behavior of the labeled material in the

plasma, one would expect that a knowledge of the total amount of injected material, and the intercept of the curve of concentration of Na^{24} at zero time, would lead to a good value of the total plasma volume. In the dog, Gellhorn *et al.* (12) were unable to obtain reliable results by the use of this method, a conclusion supported by the preliminary experiments in man of Sweet, Solomon, and Selverstone (15). This may be due to incomplete knowledge about the early part of the curve.

7. Case 5—Uptake of radioactive material in a three-compartment system

An example of this case is found in the uptake of Na^{24} by ventricular cerebrospinal fluid, follow-

ing intravenous injection. In order to determine the coefficient of transfer into the cerebrospinal fluid, it is not necessary to accept any hypothesis as to the physiological basis for the time curve of isotope in the plasma; it suffices to express the curve analytically. The equations that follow have been developed on the basis of the plasma equation given in Case 4, as equation 4-7. As can be seen from the diagram in Figure 5, the conditions are not exactly identical with those assumed for Case 4. Then we assumed that the coefficient of transfer from compartment A to compartment B was equal to that of transfer in the reverse direction. As has been shown, an equation can be derived on those assumptions, which describes the time course of the tracer

FIG. 5. CASE 5: UPTAKE OF Na^{24} BY CEREBROSPINAL FLUID FROM THE PLASMA

Counts/min. in 0.1 ml in the cerebrospinal fluid is plotted on a logarithmic scale against time. The transfer coefficient k_{ab} and the sum of coefficients ($k_{ba} + k_{bc}$) can be determined from the slopes and intercepts of the second and third rate and the value of the constant term.

content of the plasma. In the case of cerebrospinal fluid, we will assume that the volume of the compartments and their Na concentration is constant.

We will represent the plasma as before by compartment A, and the ventricle as compartment B. The coefficient of transfer k_{bo} will represent the flow of Na^{24} out of the ventricle toward the cistern. Since some of the Na^{24} will find its way back to the plasma by this route, k_{bo} and k_{ba} could, if desired, be represented together as a single constant. The equations to be derived in this case do not permit their individual determination.

$$4-7 \quad P = a_1 e^{-b_1 t} + a_2 e^{-b_2 t} + \frac{1}{3} P_0$$

$$5-1 \quad \frac{dQ}{dt} = k_{ab}P - k_{ba}Q - k_{bo}Q = k_{ab}P - (k_{ba} + k_{bo})Q$$

$$5-2^* \quad Q = \frac{k_{ab}a_1}{(k_{ba} + k_{bo}) - b_1} e^{-b_1 t} + \frac{k_{ab}a_2}{(k_{ba} + k_{bo}) - b_2} e^{-b_2 t} + (k_{ba} + k_{bo})e^{-(k_{ba}+k_{bo})t} + \frac{k_{ab}}{3(k_{ba} + k_{bo})} P_0$$

5-3 At equilibrium

$$P = \frac{(k_{ba} + k_{bo})Q}{k_{ab}}$$

Figure 5 presents a smoothed curve drawn from the experimental results of Sweet, Solomon, and Selverstone (15). The same method has been applied in plotting and analyzing this curve as has been used with Figure 4. The values of the transfer coefficients can be obtained from the slopes and intercepts of the various segments of the curve, since a_1 , a_2 , b_1 , b_2 are all known, at least empirically, from the curve presented in Figure 4. It will be noted that the analysis in Figure 5 does not include the first rate of Figure 4 with its half-life of three minutes. A further test of the validity of equation 5-2 is available by comparing the slopes of the second term of equation 4-7 ($t_{\frac{1}{2}} = 19$ mins.) with the same term ($t_{\frac{1}{2}} = 9$ mins.) in 5-2. It is seen that the agreement is not good. It would perhaps be surprising to obtain good agreement under these conditions, since no account has been taken of the viscosity of the cerebrospinal fluid, nor has any allowance been made for mixing time. In so complex a system, it must be emphasized that the equations give only a formal description. Many experiments must be carried out in

order to determine whether such a mathematical description fits the physiological facts.

8. Ultra-filtration vs. secretion

Kinsey and Grant (16) in their studies on the uptake of tracers by the aqueous humor have pointed out that the equilibrium values for the components in tracer systems are not in themselves sufficient to decide what mechanism is operating. Consider Case 2 and equation 2-7, as an example of secretion

$$2-7 \quad \frac{dq}{dt} = k_{ab}p - k_{bo}q$$

Here p and q are the concentrations in compartments A and B, and return from compartment B to compartment A is excluded.

If it is assumed, as in ultra-filtration, that the barrier between compartments A and B is a simple membrane, and that the coefficient for transfer across that membrane (with respect to concentration) is the same in both directions, equation 2-7 becomes

$$6-1 \quad \frac{dq}{dt} = k_{ab}p - k_{ab}q - k_{bo}q$$

The solution for 2-7 (secretion) is

$$6-2 \quad q = \frac{k_{ab}}{k_{bo}} p_0 (1 - e^{-k_{bo}t})$$

and for 6-1 (ultra-filtration)

$$6-3 \quad q = \frac{k_{ab}}{k_{ab} + k_{bo}} p_0 (1 - e^{-(k_{ab}+k_{bo})t})$$

Since $k_{ab} + k_{bo}$ can be represented by another constant, say k_{bb} , it is not, in general, possible to decide between these two hypotheses without additional independent measurements of one of the constants. If, however, the constant in the denominator of equation 6-3 is less than k_{ab} , it is apparent that the mechanism is not one of ultra-filtration.

Another example of this problem is afforded by the uptake of Na^{24} by cerebrospinal fluid. As has been pointed out, the sum of the constants $k_{ba} + k_{bo}$ in equation 5-2 can easily be determined, but the individual values cannot be obtained independently without further measurement.

9. Precursors

Zilversmit, Entenman, and Fishler (17) have put forward a criterion that states that one compound, A, is the precursor of a second, B, if, when the specific activity of B has reached its maximum, it equals the specific activity of A. Let us examine this criterion on the basis of our

* For details of the solutions of such differential equations, see the relevant chapter in reference (5).

Case 2 which is similar to that described by Zilversmit *et al.*

Let the specific activity in A be denoted by $P_s = P/P^*$ where P^* is the total amount of unlabeled isotope in compartment A, and similarly, let $Q_s = Q/Q^*$.

From 2-1

$$\frac{dQ}{dt} = k_{ab}P - k_{ba}Q$$

for $Q = \text{maximum}$

$$10-1 \quad \frac{dQ}{dt} = 0 = k_{ab}P_sP^* - k_{ba}Q_sQ^*$$

$$10-2 \quad k_{ab}P_sP^* = k_{ba}Q_sQ^*$$

Since $P_s = Q_s$ to satisfy the criterion

$$10-3 \quad k_{ab}P^* = k_{ba}Q^*$$

Equation 10-3 states that the amount of unlabeled isotope in compartment B is in equilibrium, in agreement with the assumptions initially made by Zilversmit *et al.*

Another criterion may be found by consideration of a chain of reactions. Let $J \rightarrow K \rightarrow L$, in a series of unimolecular reactions which can be described by the basic assumptions in section 1. The rate of growth of K from J will be given by an equation with a single exponential term, as shown in Cases 2 and 3. The rate of growth of L from J, however, will be governed by an equation which requires two exponential terms to describe it, and each succeeding member in the chain, M, N, and O, will require an additional exponential term in the equation (Burton [1]). Thus, we can say, if J is the precursor of K, a single exponential will suffice to describe the growth of K from J. If our basic assumptions describe the reaction correctly, the addition of a second exponential in the expression for growth must mean a two-step process.

10. Discussion of mathematical methods

As has already been mentioned, the use of differential equations to describe steady states of this kind is not new. Indeed, Burton (1) derived his description of the steady state in 1936 with no reference to isotopes. The most general treatment of this kind is that given by Sheppard (9). Tobias (18) has derived a system of equations describing the movement of isotopes under conditions of constant volume. Burch, Threefoot, and Cronvich (19) have examined the effect of changes both of compart-

ment volume and amount of unlabeled isotope on the constants involved in such equations.

It is also possible to describe the behavior of tracer systems by the use of integral equations. Shemin and Rittenberg (20) have made use of an integral equation in order to determine the life span of the human red blood cell using glycine-labeled hemin, a case very different from those considered here, since the decrease of labeled activity is a function of the age of the red blood cell in which it is contained. Branson (21) has also used integral equations in order to describe isotope systems.

SUMMARY

Equations have been developed and discussed covering five common cases of the use of isotopes in biological and physiological systems.

ACKNOWLEDGMENTS

The author wishes to express his gratitude to Drs. J. M. Reiner and V. E. Kinsey for their stimulating comments and suggestions.

THE THERAPEUTIC APPLICATION OF RADIOACTIVE PHOSPHORUS WITH SPECIAL REFERENCE TO THE TREATMENT OF PRIMARY POLYCYTHEMIA AND CHRONIC MYELOID LEUKEMIA¹

BY HYMER L. FRIEDEL AND JOHN P. STORAASLI

(From the Department of Radiology, University Hospitals, and Western Reserve University
School of Medicine, Cleveland, Ohio)

The use of radioactive phosphorus in the treatment of disease stems from the initial studies made by Lawrence and his colleagues in 1936 (1). Since then there have been a number of reports which establish the efficacy of this form of therapy in chronic leukemia and polycythemia (2-11). These clinical reports have been issued from a number of separate institutions, indicating that independent experiences are now fairly widespread. The report by Reinhard *et al.* (12) is an exhaustive review of the clinical course of patients treated in this fashion. Similar studies by Doan *et al.* (13) and Lawrence *et al.* (14) add extensively to the data now available in the literature. It is our intention here to add to the clinical observations presented in the previous reports, but we wish particularly to emphasize the pertinent information available from the literature and from our own work which is the basis and rationale for such treatment.

The concept of treating disease with internally distributed radioactive materials is not completely new and attempts in this direction have previously been made by introducing into the blood stream some of the naturally occurring elements, such as radium. However, the invention of the cyclotron and more recently the development of high energy nuclear reactors of the Atomic Energy Commission have given considerable impetus to this concept of therapy. This is particularly true because of the wide variety of radioactive elements which can be produced by these devices, some of which have suitable characteristics (desirable half-life, proper radiation characteristics, and satisfactory chemical properties).

The rationale of treating patients with radioactive material arises from the desire to irradiate selectively certain specific tissues and to prolong

the irradiation over one or more life cycles of the cells to be irradiated. Ever since it became clear that ionizing radiation could affect malignant tumors and allied conditions in a beneficial manner, selective localization has been continually sought after. The radiation would thus be localized primarily in a specific tissue or organ, sparing the normal remaining tissue from any deleterious effect. Even when external radiation is employed, an effort is made to localize the radiation in a specific site. This is achieved with external X-rays by means of cross-firing techniques and sharply limited portals.

At the present time the outstanding example of selective localization concerns itself with the deposition of iodine in the thyroid gland and the use of radioactive iodine for treatment of diseases of this gland arises from this highly specific localization.

In the case of P^{32} , a similar though much less pronounced selective deposition exists in leukemic tissue, in the erythrocytogenic tissues in primary polycythemia, and in certain rapidly growing tumors. Moreover, P^{32} is preferentially deposited in bone, since phosphate is a continuous requirement and important constituent of bone. This further adds selective radiation to the bone marrow which, in general, is the important site of the two diseases noted above.

In addition to selective localization in the case of various radioactive elements, the differential sensitivity of cells during various phases of the mitotic cycle must be considered. If it is true that cells are affected by radiation only during certain phases of the mitotic cycle, then prolonged low-grade radiation such as that which can be achieved by the use of P^{32} may be highly desirable. The fact that rapidly metabolizing, poorly differentiated tissues are sensitive to radiation may be another important factor.

It is known that phosphorus introduced into the blood stream in the form of a readily diffusible

¹ Some of the work was performed under A.E.C. contract No. W-31-109-eng-78 with Western Reserve University. Also supported in part by a grant from the Elsa U. Pardee Foundation.

and ionizable phosphate will be available to all tissues of the body and those tissues which utilize phosphorus in their metabolic processes will rapidly take up this element. The rate of uptake and the deposition of phosphorus—and here there is no distinction between radioactive phosphorus and ordinary phosphorus—is a function of several things.

1. *The metabolic turn-over rate* will determine the rate at which a specific cellular structure will reach equilibrium with its milieu. This is dependent upon (a) the metabolic activity of the tissue, and (b) its rate of growth. The two may be closely intertwined and inseparable.

2. *The need for phosphorus*, or indirectly, the amount of phosphorus ordinarily present in any specific tissue. This will be a gross index of the prospective uptake of P^{32} .

3. *The chemical nature of the phosphorus compound*, that is, whether it is easily ionizable, bound to organic compounds, or in insoluble form, determines in considerable measure the uptake in any specific tissue. An example of an insoluble form is chromic phosphate which is made up in a suspension and after being introduced intravenously is deposited in the reticulo-endothelial system of the liver, spleen and bone marrow.

4. *The permeability of the cell membrane*. The characteristics of the membrane, the pH of the cell environment, and other factors undoubtedly contribute to the transfer of phosphorus into the cell.

If, theoretically, all tissues of the body, normal and neoplastic, had the same type of phosphorus containing constituents and the same turn-over rate, the use of P^{32} would be entirely without rationale and would correspond to external spray irradiation with X-rays. It is well known and well established, however, that normal cells of various tissue structures have different metabolic and turn-over rates and different phosphorus requirements. When P^{32} is introduced into the body, differing levels of radioactive phosphorus will thus occur in the different tissues. In addition to this, tissues in which replacement is rapid (thus producing a rapid metabolic uptake of all the elements and compounds which enter into the constituent of the cell) approach equilibrium much more rapidly than cells of lower activity and thus

achieve a higher level of radioactive phosphorus and a correspondingly higher level of radiation than the less active cell.

If we assume a constant amount of P^{32} in the vascular and intracellular fluid, then the tissue cells in any organism will have the same specific activity of P^{32} (the ratio of active to inactive phosphorus) when the organism finally reaches equilibrium. Before equilibrium is reached, however, those tissues having the more rapid metabolic rate and turn-over will contain more P^{32} or, more precisely, a higher specific activity of P^{32} will exist. If no difference in the metabolic and turn-over rate exists, then the rate at which equilibrium is approached is the same for all tissues and specific activity is the same for all tissues at all times.

In the actual therapeutic application of radioactive phosphorus certain information must be available for orientation in this means of therapy.

1. Information about the pertinent characteristics of the radiation from P^{32} and its radioactivity constants is essential.

FIG. 1.

The biological half-life is valid only after the third day, at which time 62% of the injected dose was retained. It is a composite curve of the amount excreted plus the decay of the P^{32} .

2. The known phosphorus stores and requirements of the various tissues of the body should be known. The amount and kind of phosphorus-containing compounds is important and the distribution of nuclear proteins, phosphatides, and inorganic phosphate is very helpful.

3. The turn-over rate or metabolic activity of specific normal tissues as well as neoplastic tissue should be evaluated if possible.

4. The rate at which radioactive phosphorus disappears from the body in the excreta should be ascertained. Reference is occasionally made to the biological half-life which is a composite of the rate of loss from the body together with the rate of loss by natural decay (see Figure 1). Obviously this is important in deciding about dosage determinations.

5. The biological effects of the radiation from P^{32} must be appreciated. This can be roughly divided into (a) lethal effects, (b) specific effects on sensitive tissues such as depression of the white blood cells in the hematopoietic system, and (c) other effects, such as radiation necessary to produce erythema of the skin, etc.

Characteristics of P^{32} . P^{32} has radiation and disintegration characteristics which are readily adaptable to biological purposes.² The half-life of P^{32} is 14.3 days. It emits a beta particle whose peak energy is 1.69 MEV and which has an aver-

age energy of 0.7 MEV. Thus, the peak range in tissue is about 8 mm. and the average range is approximately 2 mm. Therefore, in a large mass of tissue, the radiation is essentially localized in the tissue in which the phosphorus is deposited.

The dosage calculations of radiophosphorus, or a calculation of the energy absorbed per unit mass of tissue, are easily made and are often converted into roentgen equivalents, since a great deal of biological information is available on external radiation which has been measured by means of this unit. Since the roentgen is defined in terms of the ionization occurring in a fixed mass of air, it is possible therefore to convert energy absorbed by tissue from internally distributed radioactive elements into roentgens, sometimes referred to as roentgen equivalent physical (rep), or roentgen equivalent.

It is necessary to know the distribution of the radioactive element in tissue, that is, the number of microcuries³ per unit mass of tissue, the energy available on the average from each beta particle emitted by phosphorus, and the number of ergs corresponding to one roentgen. (This is derived from the original definition of the roentgen by introducing the energy required to produce an ion pair.) The calculations for one microcurie per gram for complete decay are as follows:

Calculation of tissue dosage in roentgens due to the complete decay of 1 microcurie of P^{32} in gram of tissue

Half-life = 14.3 days

$$\text{Average life} = \frac{14.3 \times 86,400}{\ln_0 2} = 14.3 \times 86,400 \times 1.443 \text{ seconds}$$

$$\text{Average energy per disintegration} = \text{Peak energy} \times 0.4 = 1.69 \times 0.4 \text{ MEV roentgens}$$

$$= \frac{(\text{microcuries})(\text{dis./sec./microcuries})(\text{aver. life in sec.})(\text{aver. energy in MEV})(\text{ergs/MEV})}{\text{ergs/roentgen}}$$

$$= \frac{(1)(3.71 \times 10^4)(14.3 \times 86,400 \times 1.443)(1.69 \times 0.4)(1.6 \times 10^{-6})}{83}$$

$$= 857 \text{ (roentgens for complete decay of 1 microcurie in 1 gram of tissue)}$$

²Radioactive phosphorus was first produced in the cyclotron by E. O. Lawrence by the bombardment of red phosphorus placed in the external target chamber or the bombardment of an iron phosphide probe placed in the deuteron beam (d,p reaction). Since the development of the piles or nuclear reactors now being operated by the Atomic Energy Commission, radiophosphorus is now made primarily from sulfur by the n,p reaction, producing essentially carrier-free P^{32} . It is also possible to produce phosphorus in the pile by the n, gamma reaction. The n,p reaction with sulfur obviously provides carrier-free material.

³1 microcurie is 10^{-6} curies. A curie is defined as 3.7×10^{10} disintegrations per second.

Radioassay of P^{32} . Shipments of P^{32} from Oak Ridge are in the form of aqueous solutions of H_2PO_4 at pH 3-5. These samples, properly diluted, are evaporated on a silver disc so as to approximate closely the size and activity of the deposit of the RaD + E standards distributed by the Bureau of Standards. These samples are then counted along with the RaD + E standard and absorption curves run for both. A value of the count at zero absorber is obtained by extrapolating the above curves to zero, allowing for the thickness of the G-M

AVERAGE GENERAL DISTRIBUTION OF P^{32} FOR 14 DAYS
IN 16 NORMAL ALBINO RATS

FIG. 2

The curve shows the distribution of retained P^{32} in skeleton and viscera and the amount excreted for intervals throughout 14 days. The amount retained in the skeleton progressively increases beyond the 14 day period.

Phosphorus content of normal tissue. The normal phosphorus stores of the various tissues of the body are an important consideration in the feasibility of treatment with ionizable P^{32} . Since the stores of phosphorus in the tissues generally reflect the need for phosphorus, the amount of P^{32} taken up in tissue will be directly related to this need. Bone, therefore, contains more phosphorus than any other tissue. Figure 2 indicates the character of the distribution of intraperitoneally administered P^{32} in the skeleton and the soft tissues over the first two weeks.

Cohn and Greenberg (15) found that retention of P^{32} per unit fresh weight in various tissues decreased in the following order: bone, liver, in-

testine, heart, kidney, lung, muscle, skin and brain. After 98 days, 92% of the retained phosphorus was present in the skeleton. Studies made on rats in which amounts of P^{32} were considerably greater than tracer doses, gave the distribution as seen in Table I.

The turn-over rate, or metabolic activity of various normal and neoplastic tissue. Some concept of the metabolic activity with regard to phosphorus in the various normal tissues as well as abnormal cellular growths is very important. The greater differential absorption rate in growing tissue as compared with adult tissues has been shown in tissue culture by Bulliard *et al.* (16). Comparison of the uptake of P^{32} of neoplastic and normal tissues has been made by Kenney *et al.* (17) and by Lawrence and his associates (18-21). It has been demonstrated quite conclusively that more P^{32} is present in the rapidly growing tissue than in

TABLE I
Per cent of intraperitoneally injected P^{32} present in
various tissues of albino rats

Organ	1 day	7 days	14 days
1. Skeleton	45.0	41.5	34.2
2. Muscle	19.4	10.8	16.2
3. Digestive Tract	14.4	2.5	4.2
4. Liver	9.2	1.3	1.8
5. Skin	5.4	1.4	2.0
6. Brain	0.13	0.20	0.20

normal tissue, and particularly high in neoplastic tissue. Forssberg and Jacobsson (22) found in their studies of animals with intravenously labeled phosphate that, in the case of transplanted Brown-Pearce tumors, the metastatic tumor took up as much P^{32} as other active organs (spleen, liver, kidney) and about five times as much as less active tissue (diaphragm, omentum, lymph nodes, pleura). Forssberg (23) investigated the uptake of P^{32} by bone metastases and found that these would take up much larger amounts of P^{32} per gram of wet weight than a corresponding weight of normal bone. The work of Marshak (24) in comparing the uptake of P^{32} in the nuclei and cytoplasm of normal and malignant cells indicates that the malignant cells not only accumulate more P^{32} than the normal cells, but that the relative proportion of administered phosphorus in the nucleus as compared to the cytoplasm is much greater in the malignant cell than in the normal cell. This is

tube window and additional air absorber. By comparing the zero absorber counts of the P^{32} and the $RaD + E$ standard, an absolute millicurie value is obtained for the P^{32} . This value must be corrected, however, for the difference in backscattering from silver of the beta particles of P^{32} and the $RaD + E$ standard. This correction, when applied, reduces the above absolute millicurie value by 7%. Results obtained by this method generally check with the assay of the Oak Ridge National Laboratories values to within 5%.

true not only for malignant cells but for rapidly multiplying normal cells.

Studies of the distribution of P^{32} taken up in the nucleo-protein, phosphatide, and acid-soluble fractions in normal tissues, leukemic tissues, and tumor tissues, indicate that the highest uptake was present in the nucleo-protein of leukemic and tumor cells. The differences between the various phosphatide and acid-soluble fractions were not remarkable. It is apparent that the nucleo-proteins of leukemic and tumor cells were synthesized more rapidly than those of normal cells of the mouse, and therefore incorporated more P^{32} . Since no important differences exist between the normal phosphorus content of the nucleo-protein fractions of the various tissues, the specific activity of the nucleo-proteins of the leukemic and tumor cells are therefore higher than that of normal cells.

Rate of loss from the body. Information on the rate at which material is lost from the body is vital. In order to determine the effectiveness of therapy it will be necessary to determine the amount of material actually distributed in the tissues. There are considerable discrepancies between various individuals in the amount retained. It is possible, however, to collect the excreta of patients during the treatment period and ascertain precisely the amount distributed in the body. The information which is gained in this way is difficult to apply in a practical manner. In general, it has been found

that patients excrete 5% to 25% of the administered P^{32} in the first four to six days when given intravenously, and 15% to 50% in the first four to six days when given by mouth (25). It is generally recognized that the retained dose of the material given by mouth is 75% of that given intravenously. Figure 3 shows corollary data which have been obtained in rats, indicating the rate of excretion which may be expected after intraperitoneal administration. At the end of two weeks 46% is excreted, and of the remaining, 20% is in the viscera and musculature, and 33% in the bone. The ratio of bone deposition to soft tissue deposition continues to increase with time. The figure for bone has added significance when one recognizes that bone comprises only 10% of the body weight.

It has been shown that the rate of retention in leukemic patients is higher than in normal for the first few days but it is not improbable that after the first week or ten days the excretion rates in normal and leukemia patients are comparable. In calculating dosage, the biological half-life, which is a combination of the excretion rate and the physical decay rate, is actually more helpful than the physical decay rate alone (see Figure 1).

Biological effectiveness. The biological effectiveness of radiation from P^{32} must be evaluated for each separate system in the body. However, a broad general idea may be obtained from the rate

EQUILIBRIUM AND EXCRETION CURVES FOR P^{32}
FOR 15 NORMAL ALBINO RATS

FIG. 3

The rate of excretion changes after the third day. Prior to this, the excretion is definitely more rapid and the curve has been arbitrarily called the equilibrium curve.

15 DAY SURVIVAL CURVE IN
WISTAR STRAIN ALBINO RAT
GIVEN P^{32} INTRAPERITONEALLY

FIG. 4

The LD_{50} for P^{32} given intraperitoneally is approximately 4.5 microcuries per gram in the albino rat (for a 15 day period).

of survival and in Figure 4 a survival curve is shown for rats having received P^{32} intraperitoneally. The LD_{50} for a 15 day period is about 4.5 microcuries of administered P^{32} per gram of body weight. These animals die of severe leukopenia, thrombocytopenia and anemia. There are numerous foci of infection and severe hemorrhagic manifestations throughout the body. Observations have been made with regard to the total maximum depression in the white blood count. Increasing doses show an increase in the total maximum depression. We have found in rats that 0.7 microcuries per gram of body weight produces a maximum depression of about 50% occurring in ten days.

Studies have been made of erythemas produced on the skin by Osgood *et al.* (26). The dose to produce a threshold erythema was found to be 34 microcurie hours per square centimeter.

CLINICAL RESULTS WITH P^{32}

In the past two years, over 50 patients have been treated with radioactive phosphorus at the University Hospitals of Cleveland. In this number

are included the chronic leukemias (myeloid and lymphatic), primary polycythemia, several acute leukemias in children, a selected group of breast carcinomas which have metastasized widely to bone, and a small number of miscellaneous conditions in which it was thought desirable to observe the effect of P^{32} . There were no cases of Hodgkin's disease or lymphosarcoma since the experience with these diseases is, at best, uncertain when treated by P^{32} and because their response to X-ray, at least in the earlier stages of the disease, is generally good. In addition, the treatment of ordinary uncomplicated lymphoid leukemias with P^{32} has been avoided since the bone marrow, although infiltrated with lymphoid elements, is not hyperplastic and the normal elements of the marrow receive unnecessarily heavy radiation. The six cases of lymphatic leukemia included in this study were those which had failed to respond to previous X-ray or were cases in which the disease was so widespread that the immediate outlook was very poor. This accounts for the fact that all the patients with lymphoid leukemia were dead within seven months following the beginning of P^{32} therapy. All the patients reported here had sternal marrow biopsies showing marked displacement of the normal marrow elements by mature and immature lymphocytes.

As has been demonstrated by others, primary polycythemia show excellent response to P^{32} . The response in this group is followed closely by that occurring in chronic myeloid leukemias after treatment with phosphorus.

The cases of acute leukemia, all occurring in children, in general responded very poorly. One individual, however, received definite beneficial effect with a remission which lasted for almost a year—the patient dying at the end of this period. There were widespread destructive lesions in bone which showed considerable improvement following therapy.

It is our intention here to report in detail the primary polycythemia and chronic leukemias since these have received greatest attention in the literature previously and for which the broadest background exists.

Polycythemia rubra vera. Ten cases of primary polycythemia have been treated with radioactive phosphorus. Table II gives a brief summary of the clinical and hematological data for each pa-

POLYCYTHEMIA RUBRA VERA

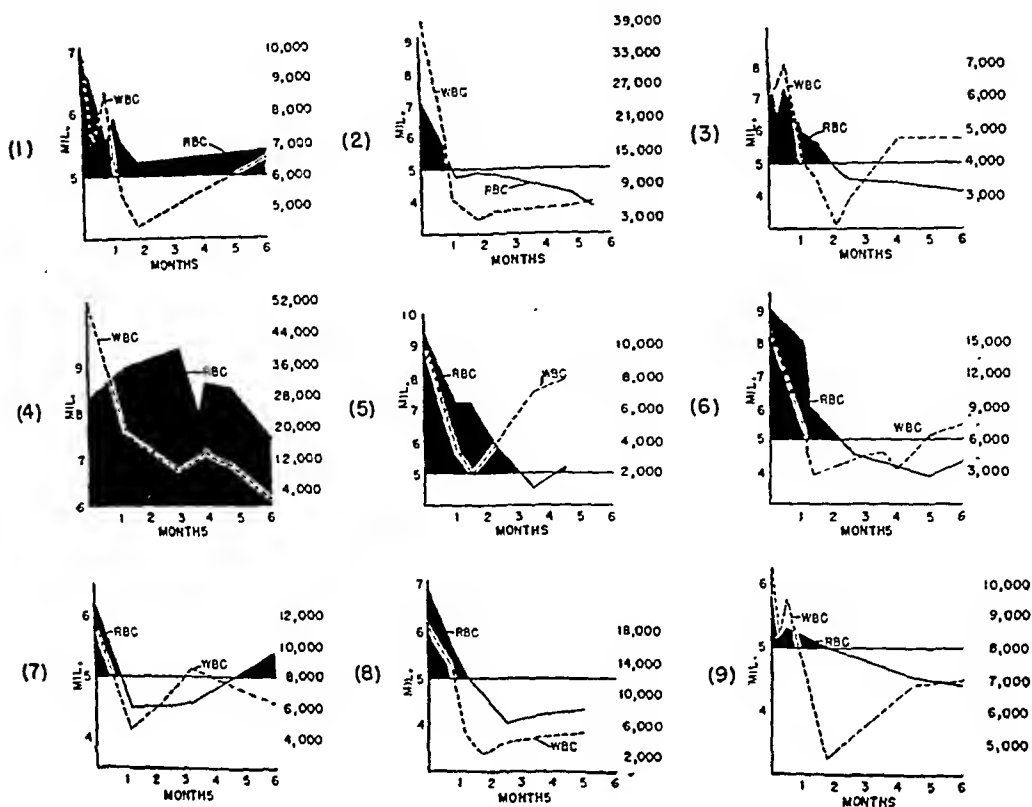

FIG. 5

These curves are the initial hematological responses to P^{32} of the first nine cases. Case 10 was omitted because death occurred before complete hematological response was obtained.

tient, and Figures 5 and 6 give graphically the initial hematological response of the first nine patients and a composite average response of the group.

In Table II it may be observed that all cases had initial red blood cell counts ranging from 6.21 to 9.4 million per cubic millimeter of blood; the hematocrits range from 51% to 77% (Wintrobe method) and the platelets were either normal or increased in number. In the majority of the cases the white cell counts were above normal. In all but two cases a palpable spleen was present. The sternal marrow biopsies showed normal or hyperplastic cellularity.

The response to P^{32} was reasonably prompt. The peripheral blood counts showed definite evidence of response at about one month and the response was maximum in a period of approximately three to four months. Coincidentally, an immediate depression of the white cell count occurred. The average initial white blood cell count was

19,000 per cubic millimeter and leveled off just above 5,000 white blood cells per cubic millimeter after treatment (see Figure 6). In two of our cases, marked depression of the platelet count was demonstrated. This was accompanied by purpura and spontaneous dependent ecchymosis (Cases 2 and 8). In Case 2, this occurred after the third course of phosphorus. After the initial episode, neither patient showed further evidence of hemorrhage and the thrombocyte counts returned to essentially normal levels. Two cases (Nos. 1 and 4) failed to respond adequately to P^{32} . The reason for failure in these two cases is obscure. The diagnosis of primary polycythemia in Case 1 may have been in error. Since chronic lung disease was present, it is possible that this may be a secondary polycythemia.

To date, the duration of remissions in the eight cases responding favorably ranges from four to 15 months with an average remission period of approximately seven months. However, we have

POLYCYTHEMIA RUBRA VERA

COMPOSITE CURVE INDICATING
IMMEDIATE HEMATOLOGICAL RESPONSE

FIG. 6

Case 10 was omitted from the composite curve. The patient died two and one-half months after therapy was instituted. The average maximum response in the red blood count is obtained in five months, as shown by this curve.

not yet followed these cases long enough to have a definite opinion on the length of the remission period. The indications are that these intervals will be comparable to those observed by others.

The criteria for selecting cases have concerned themselves with evidence of the typical triad of polycythemia, that is, megakaryocytic, erythroid and myeloid hyperplasia. This was present in all the cases. Cases showing less than 6 million red blood cells per cubic millimeter were not treated.

Dosage. The dosage levels for polycythemia have not been rigid or fixed. At present, a dose of 100 to 150 microcuries per kilogram administered over a period of ten days to two weeks appears to produce a satisfactory remission in the majority of cases. Occasionally the administration has been continued over a longer period of time. In general, it has been our tendency to treat polycythemia cautiously since it is not possible to gauge the dosage from the hematological response until approximately three months have elapsed. For this reason it is found necessary to repeat the course in some of the cases after this period of time.

Chronic myeloid leukemia. To date, 15 cases of chronic myeloid leukemia have been treated with P^{32} . Table III gives the clinical and hematological course for each patient. Of the 15 cases,

two failed to respond to treatment with P^{32} in what was considered adequate doses. In Case 10, treatment was stopped because of marked depression of the platelets. At the time of treatment this individual also exhibited a blastic phase of the disease. (It is well known that in this stage the disease becomes refractory to any form of therapy.) The reason for failure in Case 13 is not clear. Since marked splenic enlargement existed, P^{32} therapy was stopped and X-ray given to the spleen with satisfactory results. In the remaining 13 cases, immediate and excellent response was obtained in the white blood cell count and associated with this, a rise in the red cell count was noted in most cases. As is shown in Table III, the maturation of the cells definitely changed, with a clear-cut decrease in the immature cells in practically every instance following treatment. (Arbitrarily we have considered those cells ranging from the early blastic stages to and including the myelocytic stage as immature.) It may also be seen that the average initial white blood cell count was 170,000 per cubic millimeter, ranging from 69,000 to 299,000, and following treatment a composite of the maximum response showed a drop to 17,000 cells per cubic millimeter of blood. The initial red blood cell count was 3.1 million per cubic millimeter and at the end of three months the average red blood cell count rose to 4.1 million cells per cubic millimeter.

In our series of cases, the platelet counts were relatively unaffected during the first course of treatment. This observation agrees with those of Warren (7), who stated that the megakaryocytes showed little damage with moderate dosage. However, subsequent courses tend to depress the platelet count and the rate of decrease in the platelets serves as an important criterion for the continuation of treatment. Figure 7 shows graphically the initial response of the white and red cell count for each patient. It is noted that a uniform reduction of the white cell count occurs promptly as well as a clear-cut increase in the red cell count. Figure 8 is a composite curve of the initial response to P^{32} .

A gradual reduction in the size of the spleen occurred in all 13 cases. In several the decrease was dramatic. Anorexia and weakness, the most common and distressing symptoms, disappeared at

† Immature includes early blastic stages to and including myelocytic stage. Mature includes metamyelocytes to and including segmented neutrophils.

a comparatively early date. The duration of remissions ranged from two to 12 months with an average of about 4.5 months.

In studying the cases it appears that the treatment of chronic myeloid leukemias with P^{32} is highly satisfactory, but that treatment solely by this means for all relapses is of dubious wisdom and perhaps to be discouraged. In those cases with

splenic enlargement which do not respond, or at best respond poorly to P^{32} , it is often advisable to treat the spleen with X-ray when a relapse occurs. It is our strong impression that the continued and persistent use of P^{32} for every relapse will lead to a hyperplastic bone marrow in a great percentage of cases. It is probably advisable to intersperse other forms of therapy, such as localized X-ray, or ar-

CHRONIC MYELOID LEUKEMIA

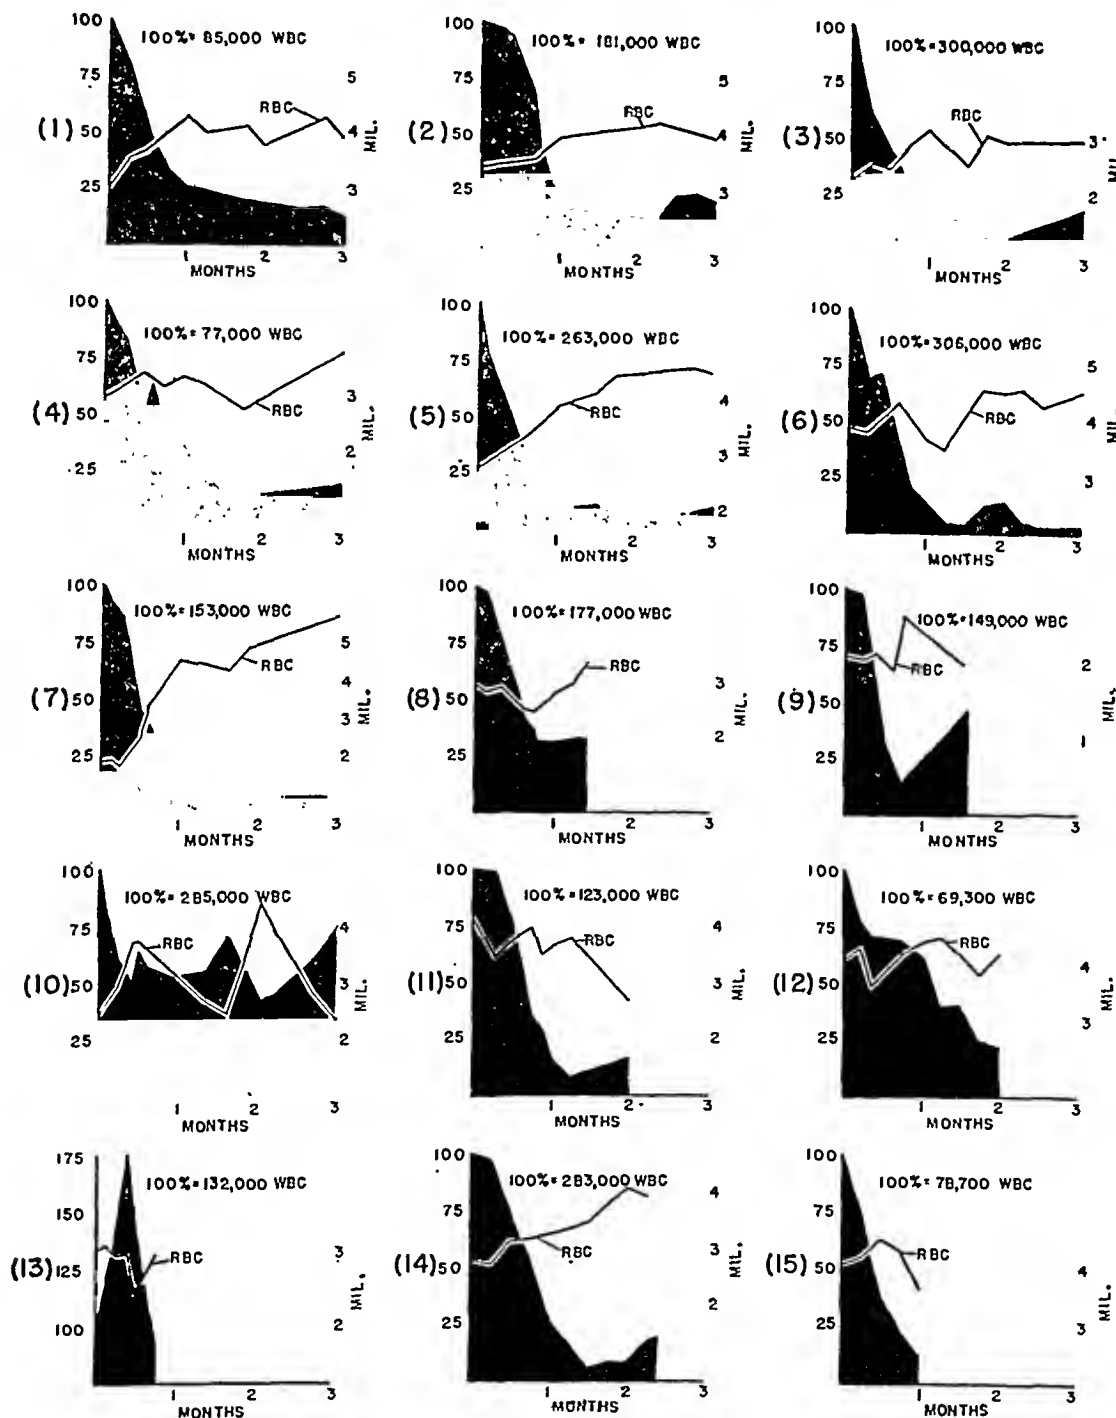

FIG. 7

These curves show the initial hematological response to P^{32} in all 15 cases.

CHRONIC MYELOID LEUKEMIA

COMPOSITE CURVE INDICATING
IMMEDIATE HEMATOLOGICAL RESPONSE

FIG. 8

Cases 10 and 13 were omitted from this curve. These cases show no response to treatment.

senic (if it proves effective), to increase the intervals between periods of P^{32} therapy.

The criteria for selecting patients have been based upon:

1. *The level of the white cell count.* No cases having counts of less than 20,000 white blood cells per cubic millimeter of blood were accepted for treatment.

2. *The thrombocyte level.* The number of thrombocytes is very important. The patients with low platelet counts were generally treated cautiously or not accepted for treatment. If the platelet count appeared to drop rapidly, treatment was often discontinued for a short interval. During the first course unusual thrombocyte depression does not appear to be a problem, but on re-treatment for subsequent relapses the thrombocyte level must be carefully observed.

3. *Character of the bone marrow.* We have been insistent that the bone marrow show definite hyperplasia before treatment was given.

4. *Maturation of the white cells.* The degree of immaturity to the present has in no way affected our selection of cases for treatment, but if

the number of immature cells are unusually high, one must always consider the approach of an acute blastic phase of the disease which is known to respond poorly.

Of the 15 cases treated with P^{32} , seven are living. The average duration of life in those patients that have died is 3.5 years. This corresponds favorably with the duration of life in a recent report made by Lawrence (14).

Dosage. Again, no hard and fast rules have been applied. It has been found that doses of 1.5 to 2 mc. given at weekly intervals usually produce the desired response after administration of a total dose of 8 to 12 mc. When the white blood cell count approaches 20,000 per cubic millimeter, treatment has been discontinued. As noted by Lawrence (14), it is probably unwise to bring the white blood cell count to normal levels since an effort to depress the white cell count to a normal level requires additional phosphorus and the risk of thrombocytopenia, anemia and serious leukopenia is increased. In the 13 cases which showed satisfactory response, the average dose required to effect hematological remission was 10.7 mc. over a period of 34 days. If one should wish to use a single large dose, there is probably enough experience accumulated in the past ten years to permit treatment of these patients in this manner, but the distribution of P^{32} over a period of a month permits integration of the white blood cell response, and fractionation of the dosage is unquestionably the preferred method of treatment.

Chronic lymphatic leukemia. As has been stated before, the rationale for treating this form of leukemia with P^{32} is not clear-cut. In the majority of cases, although leukemic infiltration is present in bone, the disease is predominantly in lymphoid tissue. The marrow does not have the hyperplasia of all the cellular elements present in myeloid leukemia and in many cases actual damage of the erythroid and megakaryocytic cells is severe. Treatment with P^{32} in most cases serves to depress a bone marrow which appears to have already suffered damage from infiltrating lymphocytic elements. The six cases of chronic lymphatic leukemia selected for treatment, as stated previously, had become resistant to X-ray or were approaching a terminal state. It is doubtful that any form of therapy would have been efficacious.

Table IV gives the clinical data of these six patients. All patients were dead within seven months after P^{32} was started. These cases all had diffuse infiltration of mature and immature lymphocytes on bone marrow biopsies. In all but two cases the initial thrombocyte counts were reduced. (Generally, low initial thrombocyte counts are contraindications to treatment with P^{32} , but in these cases it was felt that an attempt should be made to produce remission no matter how temporary.) Three of the patients were transfused during treatment. The white blood cell count per cubic millimeter of blood ranged initially from 111,00 to 719,000 with an average of 376,000. After treatment the white cell count averaged 78,000 per cubic millimeter, indicating a fair hematological response to P^{32} . As was anticipated, in a number of the cases treatment was stopped because of purpura or extremely low platelet count. It is doubtful whether P^{32} alone contributed to the purpura, since two cases had initial hemorrhagic tendencies prior to therapy.

Case 2 is of interest in one respect which deserves mention. A marked hemolytic phenomenon which was present initially showed dramatic cessation following therapy with a concomitant and unusual response in the white cell count which dropped from 216,000 to 8,000 in only 14 days, after a total of 6 mc. of P^{32} .

Widespread metastases to bone arising from breast carcinoma. Fourteen cases of widespread carcinomatosis of bone from primary breast carcinoma have been treated with what may prove promising results. These cases are to be reported elsewhere and are, therefore, not included in detail in this report. The rationale for treating these cases is based on a well-established fact that malignant tumor cells have a greater P^{32} uptake than most normal cells and that selective uptake of phosphorus in bone is large compared with other tissues, thus producing long-continued selective irradiation of bone. The most striking feature is the relief of bone pain following the treatment. It is not possible at this time to have any definite opinion as to increase in longevity of these patients. In at least one case there was marked deposition of calcium in destructive lesions demonstrated by X-ray. In others the osteoclastic process appeared to be arrested. In all these cases the dosage of P^{32} was pushed to considerably higher levels

at the risk of producing anemia, thrombocytopenia and severe leukopenia. From 18 to 20 mc. were administered in three to four weeks—two cases showing severe purpuric manifestations which subsequently improved. All cases had a moderate to marked depression of the white blood cell count which gradually returned to levels approaching normal after three months.

Treatment of this type with comparatively large doses begins to assume a heroic aspect, but the gravity of the process may justify such an approach if the therapy has promise of any beneficial effects.

DISCUSSION

There is ample evidence experimentally and by empirical clinical application in chronic leukemias and polycythemias that radiophosphorus is an important and effective means of treating these conditions. The cases of polycythemia and leukemia reported here corroborate the promising findings reported by others.

It appears that polycythemias respond unusually well to P^{32} but it is well to remember that this disease is a long-standing chronic process which can be controlled by venesection, although with some difficulty. The apparent superiority of P^{32} over other methods (X-rays, phenylhydrazine and venesection) must be weighed against the possible complications of P^{32} treatment. These are possible thrombocytopenia, leukopenia and anemia. It is still difficult to say what the eventual long time results may be with continued P^{32} application. It appears true that the duration of the remissions, the lowered incidence of the complications of the disease, and the hematological response are quite striking and superior to other means of therapy. It may well be true that P^{32} is the treatment of choice.

In the case of chronic myeloid leukemia the response is prompt, the remissions are of considerable duration and the complications, at least with moderate dosage, appear to be minimal. It is also clear, however, that it is not possible to eradicate the disease with radiophosphorus and an effort to destroy every vestige of leukemic infiltration would irreparably damage the hematopoietic system and perhaps other systems. It is therefore, unwise, as noted previously, to make any such attempt and the use of P^{32} should be limited

TABLE IV

Chronic lymphatic leukemia

to inducing remissions with as little phosphorus as possible. The impression is strong that continued application of P^{32} for every relapse with amounts required to bring the leukocyte count to low levels would undoubtedly severely injure the bone marrow and would result in an aplastic marrow in many cases. The use of radioactive phosphorus has several advantages over X-ray in that:

1. Patients have no radiation sickness.
2. The administration of radiophosphorus is simple.
3. It may have the theoretical advantage over X-ray in that phosphorus tends to seek out the most active cells and also selectively irradiates the bone marrow which in the case of chronic myeloid leukemias is, in most instances, the most important site of the disease.

P^{32} cannot be employed without a thorough knowledge of the effects of its radiation, the character of its distribution in tissue, the consequences of possible over-dosage, and clinical course of the patient. Although P^{32} has been used for over ten years, it is not yet completely removed from the realm of experiment. A great many hiatuses exist in the information concerning the effect of P^{32} .

In the case of chronic lymphatic leukemias, satisfactory results have been reported by others, and radiophosphorus is unquestionably useful in this disease. It is our opinion, however, in reviewing the appearance of the bone marrow and the general character of response of patients treated with P^{32} , that lymphatic leukemias should be spared the intensive radiation of the bone marrow which occurs with P^{32} . The appearance of the bone marrow in this disease generally indicates that hyperplasia is not present and that the erythroid and megakaryocytic elements may actually be damaged.

The application of P^{32} for widespread malignancies must be considered purely experimental. In general, treatment of these conditions with P^{32} has been poor.

The dosage of P^{32} is still not fully standardized. The amount of phosphorus administered is gauged primarily by the clinical response, by the size of the patient, by the extent of the disease and by careful observation of the known complications—leukopenia, anemia, thrombocytopenia. In general

we have, as noted above, used a routine of approximately 2 mc. a week to a total of 10 to 12 mc. for the chronic myeloid leukemias and, on the average, a total of 10 mc. in a 12 day period in the case of polycythemias. This works out to be about 150 microcuries per kilogram in a ten to 14 day period and a comparable amount in a 30 day period for chronic myeloid leukemias. In the case of chronic leukemias, fractionation is the preferred method of treatment since it permits integration of the hematological response into the treatment. In the case of polycythemia, fractionation over the period of time required for maximum responses (three or four months) would be impractical and we have, therefore, chosen to administer the dose, as have others, over a short period.

SUMMARY

1. The rationale for using P^{32} as an internally distributed source of radiation and its selective uptake by various normal and tumor tissues has been reviewed. The basis for this, which rests on experimental, biological and clinical work, is discussed.

2. The pertinent information necessary to apply P^{32} effectively is noted. Experimental and clinical data in this regard are presented. The physical characteristics of P^{32} and its behaviour biologically are included.

3. Primary polycythemias and chronic myeloid leukemias are effectively treated with radioactive phosphorus. Ten cases of primary polycythemia and 15 of chronic myeloid leukemia are reported, confirming the observations of others. P^{32} has also been used for a variety of malignant conditions other than leukemia. None of the responses have been striking. Mention is made of possible beneficial application to widespread metastases to bone from carcinoma of the breast.

RADIOACTIVE PHOSPHORUS IN STUDIES ON THE METABOLISM OF NORMAL AND NEOPLASTIC TISSUES

By A. MARSHAK

(From the Tuberculosis Control Division, U. S. Public Health Service, and College of Medicine, New York University, New York City)

Since, in the past year, there have appeared one book and three reviews covering wholly or in part the subject matter indicated above (1-3), this review will confine itself to those aspects which have not been fully presented or in which the interpretations differ from those of the present reviewer. The retention of P^{32} by various normal and neoplastic tissues has been well summarized as has phospholipid metabolism and will not therefore be considered here (4, 5).

Phosphate esters and carbohydrate metabolism

The rate of penetration of phosphate ion into muscle was shown to be relatively slow, so that the specific activity (P^{32}/P^{31}) of the inorganic phosphate (IP) within the cell was for a long time much lower than that of the extracellular IP and was shown to be a function of temperature (6). Assuming that the extracellular space for phosphorus and sodium were the same, Hevesy and Rebbe estimated that IP is incorporated into organic phosphate at the rate of $21 \mu\text{g/gm tissue/day}$ (7). Direct determination of extra- and intracellular radioactive inorganic phosphate (P^*O_4) has been made by equilibration of heart muscle slices in a medium containing (P^*O_4). The rate of penetration was $1.7 \mu\text{gP/gm tissue/min.}$ at 37°C and about $0.3 \mu\text{gP/gm tissue/min.}$ at 2°C (8) which was in agreement with data obtained earlier by Manery *et al.* (9). Equivalence between extracellular IP and that of the medium was reached in 10 to 30 minutes at either 2° or 37° , but the specific activity of the intracellular IP increased with temperature as well as with time (8). The difference in P^{32} entering the cell at 2° and at 37° indicated that cell penetration by PO_4 is not a simple matter of diffusion.

The specific activity of creatine phosphate (CP) was equal to that of intracellular inorganic phosphate while that of the labile phosphate of adenylyl pyrophosphate (APP) was lower. The terminal phosphate of adenosine-triphosphate (ATP) had the same specific activity as IP and CP, while the

remaining labile phosphorus of APP was lower by about one-half. These results were taken as evidence that intracellular IP and not total tissue IP was the source of supply of CP and APP (8). In frog gastrocnemius *in vivo* the specific activity of CP and of the labile P of the pyrophosphate fraction were found to be equal (7). Sacks and Altshuler (10) found a difference in the specific activity of IP and CP of both skeletal and heart muscle and concluded that extracellular and intracellular IP exchange through CP and APP as carriers (10). The interpretation has been criticized since their data were rather variable, since they assumed a fixed extracellular space and since they also assumed equilibrium in both concentration and radioactivity of plasma and extracellular IP (8). Bollman and Flock (11) found that in both resting and exercised limbs of the rat, the P^{32} uptake was the same for both CP and APP and there was no increase in specific activity in the recovery period. These results would be expected if the fractions were in equilibrium with only intracellular IP during the experimental period. Furchgott and Shorr (8) calculated that there is almost complete turnover of labile organic phosphorus in the cell once every two minutes.

The phosphorus groups of ATP may be designated as follows:

In contrast to the rapid turnover in P^2 and P^3 , the turnover rate for P^1 was found to be slow (12-15). Kalckar *et al.* (15) made analyses after perfusing and they found that in skeletal muscle labile organic phosphate turned over at the rate of $25 \mu\text{gP/gm tissue/min.}$ In ATP of rabbit muscle at 37° the specific activities of P^2 and P^3 were the same, while in the frog muscle at low temperature the P^2 was higher. In rabbit liver, pyrophosphate turnover was at the rate of $17 \mu\text{g/gm tissue/min.}$

Hexose monophosphate activity was either higher, lower or the same as the pyrophosphate of ATP, the variability being attributed to the extent of direct formation of phosphorylated sugar from glycogen and IP (15).

Kaplan and Greenberg (16) determined P^{32} uptake in a number of organic phosphorus compounds of rat liver. Instead of specific activity, they used the ratio of P^{32} in the fraction in question to the total acid soluble phosphorus as a measure of the P^{32} distribution in the various components of this fraction. The extracellular inorganic phosphorus was not separated or estimated so that calculations of absolute rates of turnover would be subject to considerable error (8, 15). Their data showed the uptake to be greatest in glucose-6-phosphate and lowest in glycerol-phosphate. The injection of glucose or insulin increased the level of P^{32} in ATP pyrophosphate but not in the hexose-phosphate. The greatest increase was observed after administration of both insulin and glucose. They suggested that the ATP content of the liver was of primary importance in determining the shape of the glucose tolerance curve. (High fat and protein diets decreased P^{32} esterification [16].) Sacks reported an increase in the turnover of hexosephosphate as well as creatine phosphate and adenylypyrophosphate following the administration of insulin (17). In addition, P^{32} uptake by brain tissue *in vitro* is markedly increased on the addition of glucose (18).

In general the results seem to fit the concept of a rapid turnover of phosphorus in the intracellular phosphate ester pool with a much slower turnover of inorganic phosphorus from the extracellular phase to replace phosphorus "leaking" out of the cell.

Nucleic acids and nucleoproteins

The "residual protein" of tissues is that portion which remains after the extraction of the acid soluble and lipid fractions. This has sometimes been called the nucleoprotein fraction although strictly speaking nucleoprotein is only one portion although it may be by far the greatest in this moiety.

The apparent rate of renewal of desoxyribose nucleic acid in normal rabbit liver was found to be very slow (19, 20). However, the turnover in the residual nucleoprotein of normal

liver nuclei was found to be quite rapid (21). Turnover rates for desoxyribonucleic acid (DNA) of several tissues have been calculated assuming equilibrium with intracellular IP where the latter was calculated from the Na^{24} space and the tissue IP so that calculations of absolute rates are subject to the errors previously mentioned (8, 15). The relative specific activities in order of decreasing activity were intestinal mucosa, sarcoma, spleen, liver, kidney. A regressing sarcoma gave the same DNA specific activity as one which was growing (22, 23). It was suggested that dividing or secreting cells may be more permeable to phosphate than others (1). Bone marrow DNA showed a very high specific activity and that for the thymus decreased with increasing age of the animal (24). The rate of P^{32} incorporation in DNA reported by Brues *et al.* (25) was much higher than that found by Hevesy and Ottesen (20) but was probably contaminated with RNA. Brachet (26) pointed out a parallelism between DNA turnover rate and the intensity of the nuclear alkaline phosphatase reaction.

The rate of P^{32} uptake by ribose nucleic acid (RNA) and its apparent turnover rate has been reported to be much higher than that for DNA (25, 27). In liver tissue the ratio of apparent turnover rates for RNA and DNA was found to be 30, in spleen 3 and in mucosa 2. This has been taken to indicate a high rate of actual turnover in the latter two tissues (1, 27). It may be significant that the relative RNA turnover in intestinal mucosa, spleen and liver parallels that for protein synthesis as determined with N^{15} labelled leucine (28).

Although many of the observations on P^{32} accumulation in DNA have been interpreted as indications of actual turnover, evidence had been advanced earlier that such an interpretation may not be justifiable. It has been shown that in tissue which is not mitotically active (normal liver), there is rapid movement of P^{32} containing constituents between the cytoplasm and the nucleoprotein of the nucleus so that the partition ratio remains practically constant from one hour to five days after P^{32} administration. In actively mitotic tissue (lymphoma, sarcoma, regenerating liver), however, there is a continuous rise in the partition ratio indicating movement into nuclear nucleoprotein (largely DNA) but little or none

coming out. Since the tissues to which a rapid DNA turnover has been attributed are also those in which there is rapid cell division, it is apparent that accumulation in DNA and not turnover may be the more appropriate interpretation. It would seem advisable to reexamine data on the apparent dynamic equilibrium obtained with isotopes other than P^{32} to determine the extent to which the data may be explained by cell replacement as compared with molecular turnover.

Nucleic acid turnover in relation to mitosis

Using a simple new method for isolating nuclei, Marshak (21) compared the rate of P^{32} accumulation in mouse liver and mouse lymphoma and in normal and regenerating rat liver with the rates for the nuclei of the same tissues. Initial uptake by normal liver and by normal liver nuclei was greater than that by lymphomatous tissue, but eventually the retention was much greater in the tumor tissue. Although the ratio of P^{32} concentration in liver nuclei to that in the whole liver tissue remained constant over a period of from one hour to five days after P^{32} injection, in the lymphomas studied, this ratio showed a continual increase. Sarcoma 180 gave results similar to lymphoma, while regenerating liver, in contrast to normal liver, also showed increased accumulation in the nuclei. In the nuclei of normal liver 60–70 per cent of the P^{32} was in the residual nucleoprotein with the remainder in the acid soluble and lipid fractions. Approximately the same distribution was found at various times between one hour and seven days after P^{32} administration. In the lymphomas the residual nucleoprotein contained about 95 per cent of the nuclear P^{32} . The data were taken as evidence that in the resting nucleus there is continual replacement of nuclear nucleic acid phosphorus at a rate greater than that required for complete replacement in one day. This is in striking contrast to the observations of Hahn and Hevesy on DNA extracted from tissue. Although there was obvious replacement in "resting" nuclei, with P^{32} in some form being rapidly built into the nucleic acid, and P^{32} containing components of nucleic acid also being rapidly removed to the cytoplasm, the situation in mitotic nuclei differed in that the P^{32} was built into the nuclear nucleic acid with little or none being released to the cytoplasm. Calculations from the rate of P^{32} accumulation in lymphoma nuclei showed that in 27

hours the nucleus had accumulated an amount equal to that initially present, *i.e.*, an amount sufficient to form another nucleus. This was in approximate agreement with data on rate of growth of the tumor from which it was estimated that its weight was doubled in 24 hours (21).

Brues *et al.* (25) found that between three and eight days after P^{32} administration, the specific activities of nuclear residual protein and nuclear nucleic acid were each slightly higher than that of DNA extracted from the whole tissue. RNA had a much higher specific activity than DNA in normal liver but these were approximately the same in regenerating liver. The phospholipid of the nucleus was at all times in equilibrium with that of the cytoplasm, indicating that the low DNA uptake could not be due to exclusion of P^{32} from the nucleus as had been suggested by Hahn and Hevesy. The P^{32} uptake by DNA of a hepatoma was five times greater than in normal liver, but only half as much as in regenerating liver. A correlation between increase in P^{32} incorporation in DNA and mitosis was also reported by Kohman and Rusch (29) who found a greater P^{32} uptake in nucleic acid of hepatoma as compared with normal liver. In the avian nucleated erythrocyte which does not undergo mitosis, the DNA specific activity does not decline until the erythrocytes are destroyed (30).

When P^{32} -labelled chromatin, fat-free chromatin, or that portion of chromatin soluble in 1 M NaCl were given intravenously to rats, the P^{32} was rapidly incorporated into the liver nuclei. Since the chromatin administered was particulate and could, therefore, be expected to accumulate in the liver, comparison was made of nuclear P^{32} uptake as per cent of the total liver P^{32} thus permitting comparison of nuclear P^{32} accumulation independent of the total tissue concentration. Comparison on this basis showed that nuclei accumulated over four times as much P^{32} when the source was fat-free chromatin as when it was inorganic phosphate, and twice as much as when it was phospholipid. This observation was correlated with the marked stimulation of mitosis produced when chromatin was injected into partially hepatectomized cats (31). P^{32} -labelled DNA from Jensen sarcoma was injected as a solution into rats and two hours later a considerable amount of P^{32} was found in the liver. The P^{32} concentration in the liver and kidney were about the same, while in the

spleen it was much lower. Of the liver P^{32} about three-fourths was in the acid soluble fraction (32).

Ahlström *et al.* (32) and Hevesy (1) interpreted the findings of Marshak and Walker as another example of accumulation in the liver of foreign substances injected into the blood stream. However, this cannot be accepted as a correct interpretation since the basis of comparison used, as explained above, eliminates this source of error.

The rapid P^{32} incorporation into the residual nucleoprotein of resting nuclei found by Marshak when compared with the inactivity of DNA observed by other investigators and also the efficiency of chromatin as a P^{32} donor suggested the presence of a component of nuclear residual protein which was unusually active in P^{32} turnover.

Nuclei were isolated from animals that had received P^{32} three hours earlier and it was found that on incubation at $0^\circ - 2^\circ$ very little or no P^{32} , nucleotide or nucleic acid was removed but that at 37° large amounts of polynucleotide of high specific activity were released. In saline the addition of ribonuclease (RNAse) doubled the P^{32} released while desoxyribonuclease (DNAse) gave only a 50 per cent increase. After digestion with ribonuclease, the addition of the DNAse released no more P^{32} than did native nuclear enzymes under the same conditions although very large amounts of unlabelled polynucleotides were liberated by the DNAse. The same results were obtained with normal and with regenerating liver. These observations therefore indicated that during the three hours the P^{32} was in the animals, considerable amounts had been incorporated into nucleic acid but none into DNA. When the incubation was carried out in carbonate buffer at pH 7.0 and pH 7.5, the P^{32} released was increased but the amount released in the presence of DNAse was less than when no enzyme was added and it was therefore suggested that this enzyme might bind the P^{32} containing substrate although it did not split it. In the buffer all of the P^{32} containing nucleic acid was removed by native enzymes and/or added ribonuclease, the P^{32} not so removed could be accounted for as phospholipid and acid soluble organic phosphorus. The specific activity of the P^{32} containing nuclear substrate was 13 times greater than that of the cytoplasmic RNA. It was concluded that the two are functionally different substances although the substrate material might be the same as that fraction which could be iso-

lated from nuclei by methods used for obtaining RNA, since they both had about the same specific activity. Since the nuclear autodigestion products were polynucleotides, it could be concluded that the nuclear enzymes involved were not the same as ribonuclease. Solubility studies showed that the P^{32} containing substrate differed from desoxyribonucleoprotein. Since P^{32} first appears in this nucleoprotein in mitotic cells and does not appear in DNA until some time later, this material was considered to be the precursor of DNA in such cells. Earlier experiments had shown that in resting cells (normal liver) there was rapid exchange between nuclear and cytoplasmic P^{32} and not unidirectional accumulation by nucleus and DNA as in the case of mitotic nuclei (21). Under these conditions therefore the higher specific activity of the nuclear substrate indicated that in the resting cell it was the precursor to cytoplasmic RNA (44).

X-ray effect on nucleic acid turnover

Marshak (21) showed that low doses (200 r) of X-rays produced an increase in the relative amount of P^{32} accumulated by nuclei of a mouse lymphoma although the total tissue uptake remained unchanged. Since the total tissue P^{32} was not altered, the observations could not be attributed to changes in permeability. The increase in nuclear P^{32} concentration varied with the dose. Since this effect was not observed in normal liver, the phenomenon was considered to be somehow associated with mitosis.

Euler and Hevesy (33) subsequently studied the effect of X-rays on the Jensen rat sarcoma. They found no significant effect with doses of 77–450 r on P^{32} concentration in total nucleic acid of the tumor. At doses of 450–7,000 r, the nucleic acid P^{32} as per cent of the liver IP and plasma IP was much reduced. The results could not be explained as effects on cell permeability since there was a parallel reduction in ratios of nucleic acid P^{32} to IP and to plasma P. This conclusion is valid only if the intracellular IP and the total tissue IP are not very different. A number of subsequent experiments gave further information on the reduction of P^{32} incorporation in DNA of sarcoma and liver, kidney, spleen and intestinal mucosa (22, 34, 35).

As in the case of the mouse lymphoma and liver (21) a correlation between the known inhibition

of mitosis and the X-ray effect on nucleic acid was established. However, there were these important differences. The significant effects observed by the Scandinavian investigators were obtained only at doses between 450 to 2,000 r and were all in the direction of decreasing P^{32} incorporation into DNA. On the other hand, the results with the lymphoma were obtained at doses between 200 and 260 r and were in the direction of increased P^{32} incorporation in the nuclei. With the rat sarcoma there was also marked reduction in the total P^{32} of liver, sarcoma, and plasma as well as of tumor IP following irradiation while in the mouse experiments there was no change in total P^{32} of the lymphoma. Experiments were performed on rats each bearing two tumors one of which was irradiated and the other carefully shielded and it was found that the non-irradiated tumor showed a decrease in DNA — P^{32} uptake almost as great as that of the irradiated tumor (22). The effect on DNA must, therefore, be an indirect one which is somehow produced by an initial systemic reaction. This explanation does not apply however to the results on lymphoma. Marshak has proposed a theory for the mode of action of X-ray which postulates an inhibition of conversion of the nuclear precursor to ribonucleic acid and correlates this inhibition with arrest of mitosis known to be produced (44).

Bone

P^{32} given as phosphate appears rapidly in bone (36, 37). Pecher showed that the relative concentration in bone as compared with soft tissue was lower than that observed with Ca^{45} and Sr^{89} which was anticipated because of the comparatively low Ca content of soft tissues (38). The concentration of P^{32} was greater in the spongy portion of bone and for this reason the specific activity of the epiphysis was at first higher than the diaphysis although, with time, this difference disappeared (39). The initial P^{32} deposition in bone was by ionic exchange with blood phosphate and the solid phase of bone, but this was altered later by the constant resorption and deposition which took place (40, 41). It has been proposed that mineral deposition occurs when a local excess of PO_4 is produced by action of alkaline phosphatase on phosphate esters to the point where the solubility product of bone salt is exceeded (42). A quanti-

tative method has been described for studying the healing of bone lesions by measuring P^{32} and Sr^{89} uptake *in situ* without disturbing the lesion and using the contralateral limb as a control. The ratio of strontium to phosphorus increased as the healing process progressed and it was suggested that this difference might be utilized in differentiation between the proliferating and calcifying stages (43). A decrease in the uptake of P^{32} , Ca^{45} and Sr^{89} by bone in rickets and an increase in their uptake on administration of vitamin D has been demonstrated by several authors.

THE USE OF RADIOACTIVE IODINE IN STUDYING THE PATHOLOGIC PHYSIOLOGY OF THYROID DISEASE

By RULON W. RAWSON

(From the Memorial Hospital and the Sloan-Kettering Institute, New York City)

It was in May, 1938 that Hertz *et al.* (1) published the first report on biological studies with a radioactive isotope of iodine. By today's standards these first studies were done under the least favorable conditions with an isotope whose half life of 25 minutes limited the studies that could be done. Notwithstanding the limitations put on these investigators they not only reaffirmed certain principles of thyroid physiology, but with other investigators, Hamilton (2), Hamilton and Soley (3), and LeBlond and Süe (4), who began working with radioactive isotopes of iodine in other laboratories at about the same time, they pioneered in a new field of investigating the thyroid. Today we have a small army of investigators bringing together a variety of disciplines, *i.e.*, physics, chemistry, embryology, physiology, histochemistry, pathology and clinical medicine in studying with radioactive iodine and other tools normal and morbid physiology of the thyroid. Many of these investigators are students whose primary interests are related to studies of normal and abnormal function of the thyroid. These students are delighted to have made available so many new technics with which to increase our knowledge of thyroid physiology. Many of the investigators in this field are interested primarily in isotopic methods and their application to studies in biology. They probably have been attracted to this field because of the unique avidity of the thyroid for iodine which makes this an ideal tissue for applying isotopic methods, and for studying the biologic effects of irradiation with such isotopes.

At the present time, it seems quite proper to ask questions such as those posed by Dr. William T. Salter preceding the 1948 Symposium on Radio Iodine at the Brookhaven National Laboratory. "1. How has radio iodine improved our knowledge of iodine metabolism and of the physiology and the therapy of the thyroid? 2. How do the results harmonize with past experience?" The purpose of this paper is to review the contributions made

to our knowledge of human thyroid disease by studies with radioactive iodine.

The earliest studies done at the clinical level by Hamilton and Soley (3) reaffirmed our previous concepts that the human thyroid has an avidity for iodine. These investigators compared the collection by the thyroid of iodine labelled with radio iodine and its excretion in the urine and feces in normal subjects and in patients having various thyroid disorders. They found that an orally administered dose of labelled iodine was absorbed rapidly and could be detected in the thyroid within 20 minutes. In normal subjects 74 to 89 per cent of the dose was excreted during a five-day period with the major portion appearing during the first 24 hours. Two myxedematous patients excreted 91 and 94 per cent in the urine during five days but at a much slower rate than did the normals. Thyrotoxic patients previously treated with iodine excreted about the same amount of iodine as did normal individuals. Fecal excretion of these labelled doses of iodine averaged only about 1 per cent of the dose. In another series of studies Hamilton and Soley (5) recorded the characteristic collection curves obtained by *in vivo* measurements for various thyroid states. The curve that they observed to be typical for normal thyroids was a smooth curve which leveled off to a flat plateau in two days. The initial collection by thyroids of hyperthyroid patients was greater and much more rapid than in normal thyroids but decreased almost as rapidly to a plateau lower than that of the normal thyroids. This phenomenon was also observed in two goiterous hypothyroid children (Hamilton, *et al.* [6]). This rapid decrease to a lower than normal plateau following an increased pickup observed in the goiterous children and hyperthyroid individuals might be attributed to the fact that these investigators were using 14 mgm. of inert iodide as carrier. This concept is supported by their failure to observe the rapid loss of radio iodine from the thyroid when a carrier dose of 0.1 μ g. of sodium iodide was given.

This explanation is further supported by the observations of Hertz *et al.* (7) who administered radioactive iodine with varying amounts of carrier iodide to patients suffering with Graves' disease at varying stages of preoperative treatment with potassium iodide. They observed that the untreated hyperplastic thyroids of Graves' disease collected 80 per cent or more of the labelled iodine if the dose was small. They also observed that with increasing time intervals after the administration of isotopic iodine there was an increasing amount of radioactive iodine in the thyroxine-like fraction of the gland.

Since these comparatively earlier observations, a number of investigators have used isotopic techniques in studying the role of iodine in normal and abnormal thyroid physiology.

Chapman *et al.* (8) have studied the collection of radio iodine by the human fetus. They administered tracer doses of I^{131} 12 to 48 hours before operation to pregnant women who because of organic disease were coming to therapeutic abortion. The intact fetus was fixed in formalin and then sectioned longitudinally, one half was taken for measurements of radioactivity and the other half was examined histologically. They observed that fetuses less than 12 weeks old did not concentrate any measurable amount of labelled iodine. In those fetuses which varied in age from 14 to 32 weeks the thyroids showed an avidity for iodine which seemed to increase with the age of the fetus. It is of interest that these investigators were able to confirm the opinion that the onset of function as measured in this manner is correlated with the appearance of definite follicles containing colloid.

Astwood and Stanley (9) studied the rate of accumulation of radioactive iodine by the thyroid in 70 normal humans. By plotting the counting rate per second obtained at a standard distance from the thyroid against the square root of the elapsed time in minutes they were able to plot a straight line which continued for about eight hours from which they were able to determine an accumulation gradient. In normal humans they found this accumulation gradient to vary between the limits of 1.5 and 36.4 with a mean of 9.3. Myxedematous patients were found to have accumulation gradients of 0.5 to 1.9 and thyrotoxic patients receiving no treatment at the time of testing were found to have gradients which varied between 17.0 and 43.6.

Keating *et al.* (10) followed the rate of radioactive iodine excretion in patients who had received 100 microcuries of I^{131} with 100 μ g. of carrier iodine. By mathematical analysis their urinary excretion curves yielded four quantities: 1. The renal fraction (that fraction of the dose excreted in the urine); 2. The disappearance rate (the proportional rate of disappearance from the blood); 3. The renal excretion rate; and 4. The collection rate (the proportional rate of disappearance into other sites than the kidneys which they interpreted as an index of thyroid collection rate). They found the renal fraction to be greater than normal in hypothyroid patients and less than normal in hyperthyroid patients. The disappearance rates they found to be less in hypothyroid patients and markedly greater than normal in patients having hyperthyroidism. The most significant variation that they observed was in the collection rates which were much less than normal in hypothyroid states and averaged six times the normal in hyperthyroid patients.

These marked variations from normal in the collection of iodine by the thyroid or the urinary excretion of radio iodine in hypothyroidism and in hyperthyroidism have prompted many investigators to use such methods of study as a means of diagnosing abnormal states of thyroid function. Quimby and McCune (11), who used *in vivo* measuring techniques, found that children who clinically were euthyroid concentrated and retained in their thyroids about 12 per cent of an administered dose of radio iodine. They found that hyperthyroid children concentrated and retained several fold the value obtained in euthyroid children whereas hypothyroid children concentrated as little as 1 per cent or less of the dose. McArthur *et al.* (12) followed the urinary excretion of radio iodine in a series of patients and observed the urinary excretion of 22 thyrotoxic patients to average 25 per cent; of 30 non-thyrotoxic patients to average 60 per cent. They reported that this method of study was of real value in excluding the diagnosis of Graves' disease in patients having hypermetabolism due to alcoholism, anxiety, compensated hypertensive cardiovascular disease, Parkinsonism, pheochromocytoma and thyrotoxicosis factitia.

Feitelberg *et al.* (13) have described a method for measuring and recording localized collections

of radio iodine. It is of interest that with this method they were able to demonstrate a functioning lingual thyroid.

Werner *et al.* (14, 15), have used *in vivo* methods for determining the per cent concentration and retention of radio iodine by the thyroid. They reported that the uptake by normal thyroid tissue is 20 to 30 per cent of the administered tracer and that any uptake of 40 per cent or more is regarded by them as diagnostic of hyperthyroidism.

Skanse and Riggs (16) reported that with radioactive iodine tracer studies they were able to make the diagnosis of thyrotoxicosis factitia in two patients who had elevated basal metabolic rates and abnormally high serum precipitable iodines. Both of these patients excreted more than 97 per cent of the radio iodine and by *in vivo* measurements were found to concentrate none in their thyroids. Rawson and Skanse (17) have called attention to the fact that thyrotoxic patients who have previously received "priodax" for x-ray visualization of the gall bladder excrete most of the radio iodine given within an indefinite period of time following cholecystography. Such patients, if clinically thyrotoxic, on the basis of elevated serum precipitable iodines and maximum excretion of radio iodine might be confused with patients having thyrotoxicosis factitia. This problem should be a rare one if careful physical examinations are done. In thyrotoxicosis factitia the thyroid should not be enlarged or it may be so atrophic, as the result of the ingested thyroid, as to be impossible to feel, whereas in classic Graves' disease the thyroid can be felt without any trouble by an experienced examiner.

The above studies have provided base lines which have been useful in evaluating the effect on the thyroid of various thyroid-stimulating or thyroid-inhibiting agents. They have also provided standards for certain studies which may throw light on such questions as to the genesis of non-toxic goiters in the presence of an adequate intake of iodine, the mode of action of iodides in Graves' disease, and as to the mechanism of action of the thyroid hormone.

Stanley and Astwood (18) have evaluated the effect of thyroid-stimulating hormone on the collection of radio iodine by the thyroids of normal humans. They determined the accumulation gradients in the thyroids of their subjects and followed

the effect of thyroid-stimulating hormone on these gradients. They observed that for eight hours after the injection of hormone no effect on the rate of iodine pickup could be detected, but thereafter a marked acceleration which became maximum in 24 to 48 hours occurred. This increased avidity for iodine observed in subjects after administering thyrotrophic hormone was not altered by administering mercaptoimidazole, an agent which effectively inhibits the binding of iodine to thyroid protein, *i. e.*, inhibits the iodination of thyroid hormone. This observation suggests that notwithstanding the mode of action of the thyroid-stimulating hormone, the increased rate of collection of iodide by the thyroid is not secondary to its being converted to thyroid hormone. Indeed it may be suggested on the basis of this observation that thyrotrophic hormone has increased the iodide space of the thyroid and that any increased thyroid hormone production following treatment with thyrotrophic hormone is secondary. They were unable to demonstrate any loss of stored iodine following the administration of thyrotrophic hormone. These results differ from those obtained by Keating *et al.* (19), who studied the effect of thyroid-stimulating hormone on the collection and release of radio iodine by the thyroids of chicks. These investigators observed a loss of iodine from the chick thyroid before any increased collection could be demonstrated. These differences might be explained as species differences or they might be related to dose levels. If one calculates the doses per unit weight of test animal, the chicks received doses 20 to 40 times greater than those received by the human subjects.

Stanley and Astwood (18) also observed that patients who were considered to have potentially normal thyroids and who were taking desiccated thyroid were incapable of accumulating significant amounts of radio iodine in their thyroids. They did observe, however, that patients who had been taking desiccated thyroid up to the time of receiving the thyrotrophic hormone were capable of concentrating radio iodine after thyroid-stimulating hormone had been administered. This inhibition to the iodine concentrating capacity of the thyroid by the administration of exogenous thyroid hormone might be attributed to an inhibition of thyrotrophic hormone production in the subject's own pituitary. It must be pointed out,

however, that Cortell and Rawson (20) have demonstrated that thyroxine when administered to hypophysectomized rats partially inhibits the action of administered thyroid-stimulating hormone on the thyroid. It would be interesting to compare the effects of thyroid-stimulating hormone on the accumulation gradients of radio iodine in the same euthyroid subjects before and after treatment with desiccated thyroid. Stanley and Astwood (18) suggest that this method of study might be of value in determining whether or not a patient being treated with desiccated thyroid does or does not have a potentially functional thyroid gland.

Studies with radioactive iodine have been of value not only in determining the mode of action of certain thyroid-inhibiting agents but such studies have also been of value in quantitating the effects of a variety of these drugs. In 1943 Rawson *et al.* (21) reported a patient who had developed a large goiter, while taking potassium thiocyanate in treatment of hypertension. Biopsy of this gland showed an extreme hyperplasia. Only a small per cent of a tracer of I^{131} given to this patient was excreted in the urine. Unfortunately this observation was not correlated with the blood thiocyanate level.

Subsequent studies by Haines (22) and by Richards (23) done in several patients having "thiocyanate goiter" have revealed that the excretion of radioactive iodine by such goiterous patients can be related to the blood thiocyanate levels observed in such patients. If the thiocyanate level is elevated, most of the iodide is excreted; if it is low, less of the iodide is excreted.

Rawson *et al.* (24) used radio iodine tracer technics in evaluating the action of thiouracil on the thyroids of Graves' disease. They prepared patients for thyroidectomy by administering thiouracil. Preoperatively they gave ten of their patients tracer doses of I^{131} and determined the radioactive iodine excreted in the urine and that recoverable in the operatively removed thyroids. They found that most of the tracer iodine was excreted in the urine and that only a small per cent was contained in the thyroids. They concluded that this drug acted to interfere with the synthesis of thyroid hormone by setting up a block to the collection or the utilization of iodide.

Studies done by Stanley and Astwood (25)

have demonstrated that in thyrotoxic humans the thiouracil group of drugs causes an inhibition to the organic bindings of iodine (which must first have been accumulated by the thyroid as iodide) to thyroid protein. By measuring with *in vivo* methods the pickup of radio iodine by the thyroid they were able to demonstrate that the thyroid, though well controlled by the administered drug, was capable of concentrating iodide in the thyroid. That this collected I^{131} existed as iodide in the well-controlled gland was evidenced by the fact that the administration of large doses of potassium iodide resulted in a sudden decrease in the activity over the thyroid. They also demonstrated that the administration of potassium thiocyanate resulted in a prompt discharge of accumulated iodide from the thyroid. It is interesting that bromide was observed by these investigators to have no effect on the collected iodide. Patients receiving thiouracil or related agents in doses inadequate to control their thyrotoxicosis when injected with potassium thiocyanate were found to discharge only a fraction of the accumulated radio iodine and were concluded to be receiving inadequate amounts of the drug to inhibit the binding of iodine to the thyroid protein. It has been suggested by Stanley and Astwood (25) that this method of study would be of value in determining the adequacy of dose in patients undergoing treatment with any of these agents. On the basis of these observations it is apparent that the first step in storing iodine in the thyroid is that of concentrating it as iodide in an iodide space or trap. It would appear from these studies that the pickup of iodide is not dependent upon the rate of iodination of the hormone. On the other hand we have observed that the pickup of iodine by the thyroids of rats under the influence of thiouracil is only a fraction of that collected by thyroids of untreated controls even at 10 minutes after administering the tracer iodine. Notwithstanding this demonstration that the iodine is first concentrated as iodide we still do not understand the mechanism by which the iodide is accumulated in the thyroid nor are we able to explain the increased avidity for iodine by the hyperplastic thyroids of Graves' disease nor by the thyroids of animals previously treated with thyrotrophic hormone.

Stanley and Astwood (26) have compared and quantitated the thyroid-inhibiting properties of

several goitrogenic agents on the thyroids of human subjects. The method that they used depended on the capacity of these agents to modify the accumulation gradients of radioactive iodine by the thyroids as detected by serial counts with an externally placed Geiger-Mueller counter. The values obtained by these investigators are considerably different from those obtained by methods which depend upon the goitrogenic effects of these drugs in rats. For example, whereas propyl thiouracil has goitrogenic properties in the rat which are 10 times those of thiouracil, by this method of assay propyl thiouracil has only 0.75 the activity of thiouracil. Likewise, thiourea, an agent possessing only 0.1 the goitrogenic activity of thiouracil in the rat is equally as effective as thiouracil in altering the accumulation gradient in human thyroids.

Rawson and McGinty (27, 28), who compared the minimal doses of various injected drugs necessary to inhibit significantly the concentration of radioactive iodine in the chick thyroid found that propyl thiouracil was no more effective than thiouracil whereas by tests of goitrogenesis in the rat propyl thiouracil was 10 times more active than thiouracil. These same investigators found that benzyl thiouracil was 10 times as effective as thiouracil in inhibiting the concentration of radioactive iodine in the thyroid of a chick. Stanley and Astwood (26) found this agent in their studies on the human to have 0.75 the activity of thiouracil. McGinty and Wilson (29) have applied the methods of Stanley and Astwood in quantitating the effects of these agents on the thyroids of the Rhesus monkey. They have found the monkey thyroid to respond like the human thyroid, both qualitatively and quantitatively to these various thyroid-inhibiting agents. On the basis of these observations we might suggest then that agents would best be quantitated on the monkey with the method described by Stanley and Astwood before being subjected to clinical trial in the human by the same method. The final test of clinical usefulness will depend of course upon testing such drugs on patients having thyrotoxicosis. The need for this final test is demonstrated by our own observations that benzyl thiouracil, which when tested in the rat and the chick seemed to be a very active agent and when tested by the method of Stanley and Astwood had about the same activity

as propyl thiouracil, was ineffective in controlling thyrotoxicosis in a small series of patients.

The mechanism by which the various salts of iodine exert their well-known therapeutic effect in Graves' disease has long remained unexplained. Indeed when one considers that the thyroid of untreated Graves' disease has an increased avidity for iodine which it rapidly converts and secretes into the circulation as thyroid hormone, the administration of iodine to such patients would seem to be an unwise maneuver. However, notwithstanding these theoretical contraindications, the therapeutic value of iodine in Graves' disease is a well-established fact. Plummer (30) who established the value of this therapeutic measure advanced the hypothesis that the toxic effects of Graves' disease were due to the elaboration of an incompletely iodinated hormone molecule. He suggested that the therapeutic action of iodine in this disease resulted from complete iodination of the hormone which even in excess was less toxic than the abnormal hormone.

In contrast to the two-hormone theory advanced by Plummer (30), Rawson *et al.* (31) have advanced a theory that iodine has two actions on the thyroid, an iodinating or a nutritive action and an involuting action on the thyroid of Graves' disease and have reported that they had been able to separate these two actions of iodine on the thyroid. They studied patients having Graves' disease before any medication was given, after treatment with thiouracil had caused a fall in the basal metabolic rate to a normal level, and after iodine had been added to the regime of treatment with thiouracil. Observations included micro-histometric studies of biopsy specimens taken before treatment, after treatment with thiouracil, but before administering iodides, and of glands removed at operation after treatment with both drugs. The urinary excretion of radioactive iodine was determined before and during treatment with thiouracil. Total and thyroglobulin iodines were determined in the operatively removed thyroids. The results showed hyperplasia of the thyroid samples removed before starting treatment with mean acinar cell heights which averaged 12.0 micra. There was an increase in thyroid hyperplasia after treatment with thiouracil, the mean acinar cell heights averaging 13.9 micra. However, involution was observed after iodine had been adminis-

tered in addition to thiouracil, the average mean acinar cell height decreasing to 7.2 micra. This involution occurred even though the thyroids were not utilizing the iodine in the synthesis of thyroid hormone as evidenced by urinary excretions of radio iodine during treatment with thiouracil which averaged 80 per cent as contrasted to average radio iodine excretions of 25 per cent before beginning treatment. The failure of such glands to utilize iodine in the synthesis of thyroid hormone is further supported by the thyroglobulin iodine values which in the glands taken from patients who had received thiouracil and iodine averaged 7.0 mgm./100 gm. of fresh thyroid tissue. The average thyroglobulin iodine of a comparable series of patients who had been prepared for operation with thiouracil alone was 6.8 mgm./

100 gm. of fresh thyroid tissue, of normal human thyroids 29.8 mgm. per cent, of a small series of patients treated with iodine only, 36.6 mgm. per cent.

All of the iodine administered to one patient was labelled with radioactive iodine and thus a balance study was made. Before treatment only 16.3 per cent of a tracer dose was excreted. After treatment with thiouracil 0.8 gm. daily for 15 days, 73.5 per cent of an identical dose of radio iodine was excreted. Following the second biopsy taken from the thyroid, a daily dose of 300 mgm. of sodium iodide labelled with 100 microcuries of radioactive iodine was administered in addition to thiouracil 0.8 gm. daily. The radioactivity demonstrated in the urine excreted during and after the 10 day period of treatment with thiouracil and

FIG. 1. RADIO IODINE BALANCE IN PATIENT BEFORE TREATMENT WITH THIOURACIL, DURING TREATMENT WITH THIOURACIL AND DURING TREATMENT WITH THIOURACIL AND SODIUM IODIDE

Intake above the line. Urinary excretion below. With regard to intake plain white columns indicate that tracer iodine was given with a carrier of 150 gamma of non-radioactive sodium iodide. Stippled columns indicate that radioactive iodine was given as tracer for therapeutic dose of 300 mgm. daily of ordinary sodium iodide. (From Rawson, Moore, Peacock, Means, Cope and Riddell, *J. Clin. Invest.*, 1945, 24, 875.)

labelled sodium iodide practically equalled the radioactivity administered. See Figure 1. The radioactivity demonstrated in this patient's operatively removed thyroid was too little to measure and the thyroglobulin iodine value was only 2.3 mgm. per cent. Notwithstanding the fact that this gland failed to accumulate or to convert the administered iodine to thyroglobulin, the thyroid tissue examined after treatment with sodium iodide was well involuted in contrast to an extreme hyperplasia observed in the biopsy specimen taken just before adding iodine to the treatment. See Figure 2. This separation of the involuting action of iodine from its nutritive action, these investigators believe, may explain the paradoxical effect of iodine in Graves' disease. They also suggested that the involuting effect of iodine in Graves' disease was due to an inhibitory action of this agent to the action of thyrotrophic hormone on the thyroid cell.

Space will not permit further discussion as to the mechanism of this involuting action of iodine on the thyroid. However, attention should be

called to the reports of Wolff and Chaikoff (32), who by using tracer techniques have demonstrated in rats that the maintenance of an inorganic blood iodide level of 200 μ g. per cent or more interferes with the organic binding of iodine by the thyroid. They suggest that the level of plasma iodide is part of a homeostatic mechanism which governs hormone synthesis in the normal gland.

Although there is good evidence that endemic goiter is due to a deficiency of iodine intake, it is difficult to explain the development of such non-toxic goiters in certain patients who apparently have an adequate intake of iodine. Many students of thyroid disease have suspected the existence of positive goitrogens which play a role in the development of some of the non-toxic goiters developing in subjects whose iodine intakes by accepted standards are more than adequate. Greer and Astwood (33) have demonstrated that certain foods have an inhibitory effect to the accumulation of radio iodine. They have evaluated the effects of 61 different food substances on the "accumulation gradient" of radio iodine in normal hu-

FIG. 2. HISTOLOGIC SECTIONS TAKEN FROM BIOPSY SPECIMENS AND OPERATIVELY REMOVED THYROID IN PATIENT TREATED WITH THIOURACIL AND THIOURACIL PLUS SODIUM IODIDE

A. Histologic section of biopsy specimen taken before any treatment. Mean cell height 15.3 ± 0.14 .

B. Histologic section of biopsy removed after treatment with thiouracil had caused a fall in the B.M.R. to a euthyroid level. Mean cell height 17.3 ± 0.17 .

C. Histologic section of operatively removed thyroid after treatment with thiouracil and iodide. Mean cell height 10.3 ± 0.07 .

(From Rawson, Moore, Peacock, Means, Cope and Riddell, *J. Clin. Invest.*, 1945, 24, 873.)

FIG. 3. A SOLID CELLULAR OR TRABECULAR ADENOMA SURROUNDED BY NORMAL THYROID TISSUE WITH AUTORADIOGRAM

A. Histologic section.

B. Autoradiogram showing no evidence of function in the adenoma. The areas of black coincide with the normal thyroid tissue.

(From Dobyns and Lennon, *J. Clin. Endocrinol.*, 1948, 8, 735.)

man thyroids, and have observed that the more active foods in inhibiting the thyroid's accumulation of radioactive iodine are rutabaga, turnips, string beans, frozen peaches, pears, peanuts, walnuts, liver, milk and oysters. On the basis of these studies we might suggest that the sporadic goiters seen in areas where the iodine intake is adequate are related to positive goitrogens contained in certain dietary products.

Radioactive iodine has been a most valuable tool in evaluating the function of certain tumors of the thyroid. Indeed studies with radioactive iodine have stimulated an interest in neoplasms of the thyroid, benign and malignant, that has probably never existed before. The benign tumors of the thyroid have been studied extensively by Cope *et al.* (34), Rawson *et al.* (35), and by Dobyns and Lennon (36). In general it can be said that the benign tumors have an avidity for radio iodine which can be correlated with the degree of histologic differentiation. The solid cellular tumors,

trabecular and tubular adenomas, which show no differentiation have been found to manifest practically no iodine concentrating capacity whereas the microfollicular adenomas which show definite but incomplete differentiation have been observed to have an avidity for iodine approaching that of normal thyroid tissue. See Figures 3 and 4. At the other end of the spectrum single adenomas have been found in patients having hyperthyroidism which was relieved by simple removal of the adenoma plus a biopsy specimen of uninvolved tissue. In these instances the radio iodine was found concentrated in the adenoma and none in the uninvolved tissue. Such tumors presented histologic pictures of hypertrophied microfollicular adenomas or frank hyperplasia. The surrounding uninvolved tissue showed hyperinvolution or decreased acinar cell heights.

Dobyns and Lennon (36) attempted to correlate the cell heights of these adenomas with their capacities to concentrate radio iodine. They found

FIG. 4. TWO FUNCTIONAL ADENOMAS OF THE THYROID SEPARATED BY NORMAL THYROID TISSUE

A. Histologic section. Adenoma above is tubular and microfollicular; below is a micro and macrofollicular adenoma which has certain characteristics suggestive of a colloid adenoma.

B. Autoradiogram in which both adenomas were observed to have low-grade iodine concentrating capacity, but much less than that observed in the areas corresponding to the normal thyroid tissue between the two adenomas.

(From Dobyns and Lennon, *J. Clin. Endocrinol.*, 1948, 8, 738.)

a certain group of hyperplastic adenomas which did not concentrate radio iodine. Such tumors showed a marked variability in their cell heights and as such resembled a group of papillary adenocarcinomas. See Figure 5. The tumors which were functioning in excess of the surrounding thyroid tissue were found to have mean cell heights significantly and uniformly in excess of the surrounding normal thyroid tissue. See Figure 6. They not only found hyperfunctioning adenomas as evidenced by an increased pickup of radio iodine, which were associated with clinical hyperthyroidism, but they also found certain small adenomas which concentrated more radio iodine and had uniformly increased cell heights as compared to the surrounding tissue in patients who had no elevation in the basal metabolic rates. Continuation of such studies may throw considerable light on the life history of hyperfunctioning adenomas of the thyroid as well as upon the history of certain papillary adenocarcinomas.

Studies of cancer of the thyroid with radioactive iodine have not only excited an unprecedented interest in this disease, but they have already resulted in a much better understanding of the biology of this type of cancer. Furthermore, this writer believes these studies have already led to improvements in treatment of this disease with the conventional forms of therapy. Hamilton *et al.* (37) were the first investigators to apply radio iodine methods in studying cancer of the thyroid. With autoradiographic technics they demonstrated that normal thyroid tissue concentrated labelled iodine in the thyroid follicle. With this same technic they studied two cancers of the thyroid and observed that the cancerous tissue was incapable of concentrating any radio iodine. The first successful attempt to demonstrate pickup of radioactive iodine by thyroid cancer was reported in 1942 and 1944 by Keston *et al.* (38) and by Frantz *et al.* (39). They administered tracer doses of radio iodine to three patients having thy-

roid tumors with bony metastases. One bony metastasis from one of these tumors, an adenoma malignum, showed an appreciable uptake of radio iodine.

In 1946, Leiter *et al.* (40) reported two cases of adenocarcinoma with functioning metastases and hyperthyroidism which they studied with radioactive iodine. One of these patients had been totally thyroidectomized in 1923. Tracer studies with radioactive iodine done in this patient demonstrated that there was no functioning thyroid tissue in the neck and that the source of hyperthy-

roidism was in the metastatic tumors. Seidlin *et al.* (41) have reported that treatment of this patient with radioactive iodine resulted in definite and lasting improvement.

Following these observations several investigators interested in using radio iodine in the therapy of cancer of the thyroid have undertaken studies with radio iodine concerning the natural avidity of various thyroid cancers for radio iodine and means of increasing the capacity of such tumors to concentrate radioactive iodine.

Marinelli *et al.* (42) have investigated with

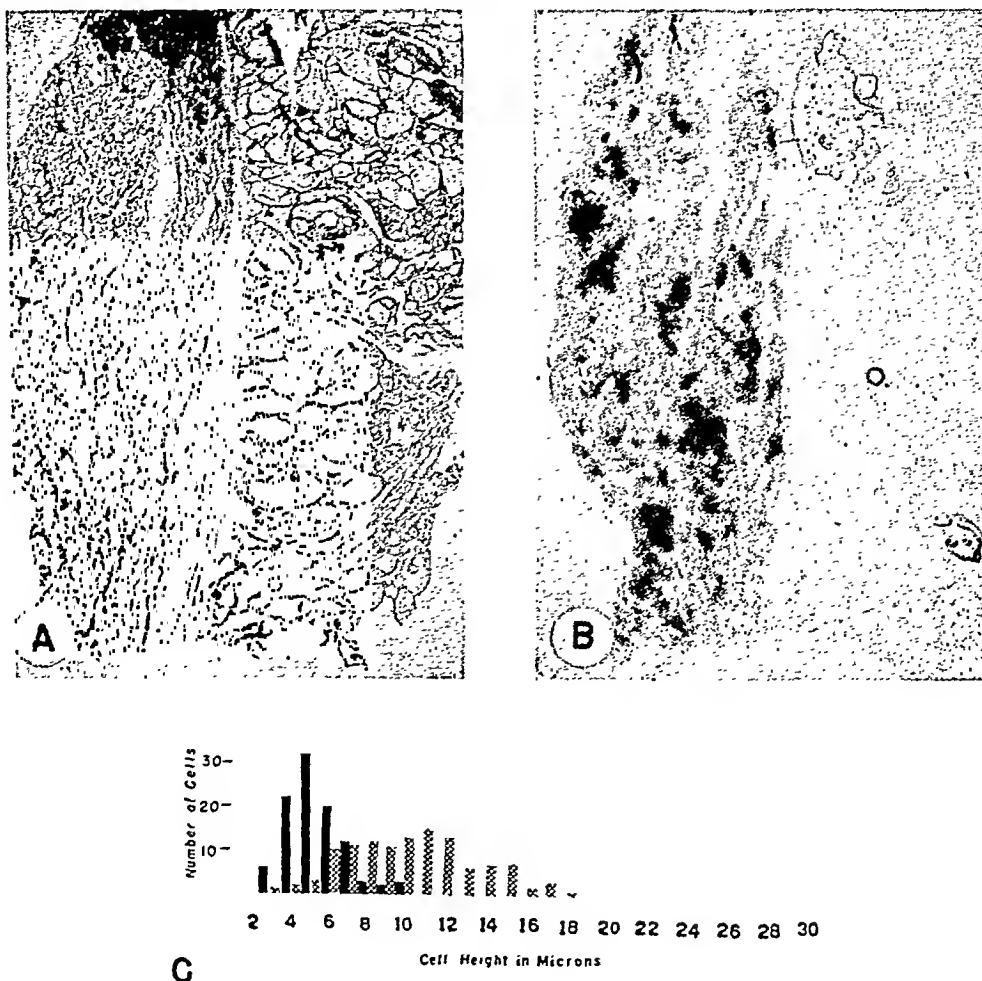

FIG. 5. HYPERPLASTIC ADENOMA WITHOUT ANY IODINE CONCENTRATING FUNCTION

A. Histologic section. Adenoma on right; extranodular tissue on left.

B. Autoradiogram showing that the radio iodine is concentrated in the extranodular tissue rather than in the adenoma.

C. Cell heights (100 cells in each type of tissue). Black columns represent the cells in the extranodular tissue; checkered cells represent the cells in the adenoma, showing an increased mean cell height but with considerable variability.

(From Dobyns and Lennon, J. Clin. Endocrinol., 1948, 8, 739.)

radioautographic technics the capacity of certain cancers of the thyroid to accumulate radioactive iodine. They studied 19 selected cancers of the thyroid and observed that 10 of these tumors possessed the ability to accumulate radioactive iodine. Five of their functioning tumors presented the histologic structure of so-called "benign metastasizing struma." See Figure 7. The remaining five tu-

mors which exhibited this evidence of function had the structure of follicular adenocarcinoma in some portion of the material studied. They concluded that pickup of iodine is closely linked with certain structural qualities, which include orderly cell arrangement in follicular pattern and the presence of colloid-like material. See Figure 8. Frantz *et al.* (43) in a study done on 32 cancers

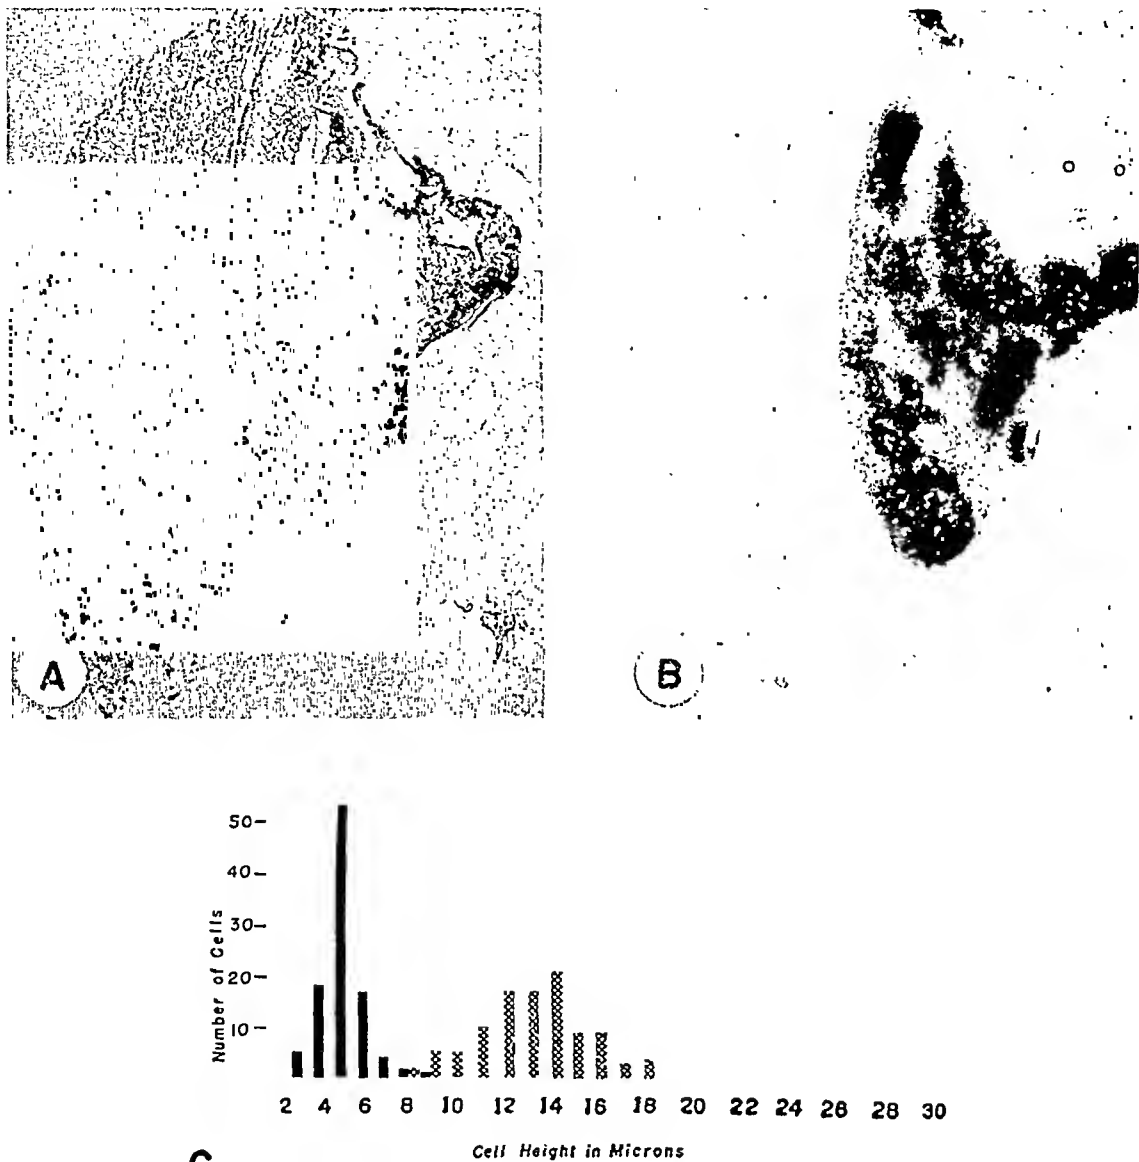

FIG. 6. HYPERPLASTIC ADENOMA WITH HYPERFUNCTION

- A. Histologic section. A roughly triangular piece of adenomatous tissue is shown on the right; uninvolved tissue on the left.
- B. Autoradiogram showing the relatively high concentration of radio iodine in the adenoma and practically none in the remaining thyroid tissue. The adenoma is interpreted as being an adenoma functioning in excess of the remaining tissue.
- C. Cell heights (100 cells in each type of tissue). Black columns represent the cells in uninvolved tissue; checkered columns represent cells of adenoma and illustrate the relative uniform cellular hypertrophy of hyperfunctioning thyroid adenomas.
- (From Dobyns and Lennon, J. Clin. Endocrinol., 1948, 8, 737.)

of the thyroid observed that seven out of 12 malignant adenomas and six mixed tumors picked up radio iodine. No pure papillary adenocarcinomas nor less differentiated cancers of the thyroid picked up the isotope.

Fitzgerald (44) reported before the Brookhaven conference that in a study of 47 selected cases of carcinoma of the thyroid given tracers of I^{131} prior to surgical removal, 20 cases showed retention of the radio iodine in some portion of the neoplastic areas. He reported that pure papillary adenocarcinomas of the thyroid did not retain the iodine. In five out of eight mixed papillary and follicular or alveolar adenocarcinomas, a retention of radio iodine was observed. He reported that two-thirds of the follicular and alveolar carcinomas stored radio iodine. Two cases of solid alveolar carcinoma stored the radioactive iodine. In six cases of Hurthle cell carcinoma and in two cases of

spindle and giant cell carcinoma he found no storage of radio iodine.

Seidlin *et al.* (45) reported that eight out of 14 patients having cancer of the thyroid were capable of collecting radio iodine. They reported that the destruction of normal thyroid tissue by radioactive iodine resulted in an increased avidity for iodine by the cancer tissue in two of three patients. They also reported that one out of two patients treated with thyroid-stimulating hormone showed an increased pickup of iodine.

Rawson *et al.* (46) have observed the effect of thyroidectomy, surgical or by large doses of radio iodine, in 21 patients having relative or absolute non-functioning metastatic thyroid cancer. Following removal or destruction of the normal thyroid eight solid and/or alveolar adenocarcinomas assumed the capacity to concentrate radioactive iodine.

FIG. 7. MICROFOLLICULAR ADENOCARCINOMA OF THE THYROID SURROUNDED BY A FEW APPARENTLY NORMAL THYROID FOLLICLES

A. Histologic section.

B. Autoradiogram made by applying this section on photographic film. It would be noted that the maximum function is demonstrated in the uninvolved normal thyroid tissue. It will also be noted that the tumorous tissue concentrated significant amounts of radioactive iodine, but much less than that concentrated by the normal thyroid tissue.

(From Marinelli, Foote, Hill, and Hocker, *Am. J. Roent.*, 1947, 58, 26.)

A case history of the first patient in whom they tried this experiment is quoted from their report:

"Mrs. T. I., M. G. H., number 48114, aged 43; was the first patient in whom this experiment was tried. She was admitted to the Massachusetts General Hospital on February 28, 1945, complaining of a soft tissue mass in the skull and of regrowth of a goiter. She gave a history of having had surgical removal in 1933 of a thyroid nodule which had existed for five years. She reported that one year before admission to this clinic she had first noted a lump over the occiput, and that six months before admission she had noted an extensive regrowth of her goiter. She was found to have a lemon-sized, moderately firm mass in the left occipitoparietal area measuring about 5×6 cm. in diameter and raised about 2 cm. above the rest of the skull. She was also found to have a walnut-sized, hard mass in the upper pole of the right lobe of the thyroid. Several large firm lymph nodes were palpable in the right anterior cervical chain. Clinically she was euthyroid and her basal metabolic rate was minus 12 per cent. X-ray studies of the chest and skeleton revealed only an osteolytic defect in the left parietal bone consistent with destruction by metastatic disease.

Tracer studies done with radioactive iodine revealed that the occipital metastasis was capable of concentrating only minimal amounts of iodine. It was reasoned that removal of her normal thyroid might be followed by a significant pickup of iodine by the skull metastasis. On March 6, 1945, Dr. R. R. Linton did a total thyroidectomy and a right radical neck dissection. At the same time a biopsy specimen was removed from the metastatic lesion in the skull. The thyroid showed a follicular adenocarcinoma. A similar picture was found in the small metastasis though this lesion showed more differentiation than the primary lesion and contained some colloid filled acini. Her normal thyroid was found to have collected 1.8 per cent of the preoperatively administered radioactive iodine per gram of tissue. The skull metastasis was found to have collected only 0.06 per cent of administered radio iodine per gram of tissue. On March 27, another tracer dose of radioactive iodine was administered and *in vivo* measurements over the metastatic lesion were made. Though the patient was found to concentrate less than 3 per cent of administered iodine in the skull metastasis, she did not develop myxedema in a period of four months. Indeed, in July 1945, her basal metabolic rate was plus 4 per cent. Hav-

FIG. 8. PAPILLARY CARCINOMA OF THE THYROID SURROUNDED BY UNINVOLVED THYROID TISSUE
A. Histologic section of papillary carcinoma of the thyroid surrounded by uninvolved thyroid tissue and encapsulated micro and microfollicular adenoma.

B. Autoradiogram made by placing Section A on photographic film. It is to be noted that the cancerous tissue in this instance did not concentrate any radio iodine. It is of interest that the benign lesion in the extrathyroidal tissue is functional and indeed concentrated more iodine than did the surrounding uninvolved thyroid tissue.

(From Marinelli, Foote, Hill, and Hocker, Am. J. Roent., 1947, 58, 23.)

FIG. 9. B.M.R. LEVELS AND RADIO IODINE COLLECTIONS BY METASTATIC TUMORS BEFORE AND AFTER REMOVAL OF THE NORMAL THYROID

It is to be noted that this patient concentrated considerably more radioactive iodine in her metastatic tumor after removal of the normal thyroid than she did before operation. It is also to be noted that four months after total removal of the normal thyroid her B.M.R. was within normal range. (From Rawson, Marinelli, Skanse, Trunnell and Fluharty, *J. Clin. Endocrinol.*, 1948, 8, 832.)

ing the erroneous impression that thyroidectomy was ineffective in altering the function of this tumor, it was decided to attempt removal of the skull metastasis. On July 6, Dr. Mixter made this attempt. However, it was impossible to do more than a partial removal of the tumor. Postoperatively the patient was treated with x-ray and received 1550 roentgens delivered in six doses through a 10×10 field. The patient returned to her home in Rochester, New York, and was not seen again until July of 1947. At that time she was taking desiccated thyroid in a daily dose of 65 mgm. (1 grain). She reported that in April of 1947 she had noted a regrowth of the tumor in her occipitoparietal area. She was found to have a moderately firm tumor, which measured about 2 cm. in diameter, at the site of the previous occipital tumor. She had a basal metabolic rate of minus 16 per cent. A tracer dose of radioactive iodine was given on July 3, of which she excreted 92 per cent in the urine. *In vivo* measurements revealed radioactivity in the skull lesion and in the neck. There was about three times as much activity in the skull metastasis as in the neck. On August 1, she was advised to stop taking thyroid. She was readmitted to the hospital in October of 1947 and was found to have a B.M.R. of minus 11 per cent. Studies revealed an increase in

size of the occipital lesion and a new osteolytic lesion in the third dorsal vertebral body. A tracer dose of radioactive iodine was administered on October 6. Of this tracer dose, she excreted only 48 per cent. By *in vivo* measurements, it was estimated that she concentrated 30 per cent of the administered dose in her occipital lesion, 10 per cent in the region of her thyroid and 10 per cent in the vertebral lesion. This patient is now being treated with large doses of radioactive iodine." See Figure 9.

The time required to observe these changes subsequent to thyroidectomy varied between one month and 32 months. In four cases of pure papillary adenocarcinoma that they studied, total thyroidectomy had no effect on the function of previously non-functioning metastasis. These same investigators have likewise reported that the avidity for radio iodine of certain functioning cancers of the thyroid can be increased by administering thyroid-stimulating hormone. They have also observed that prolonged treatment with thiouracil may be followed by considerable increase in the

iodine accumulating capacity of certain functioning cancers of the thyroid. This described effect of prolonged treatment with thiouracil might be ascribed to an increased elaboration and augmentation in action of the patient's own thyroid-stimulating hormone.

These observations in which it has been demonstrated that the function of metastatic cancer of the thyroid can be altered by removal of the normal thyroid or by administering thyroid-stimulating hormone suggest that this cancer is not wholly autonomous but is capable of responding to certain physiologic stimuli. They also provide us with concepts which may lead to a more complete understanding of the biology of this type of a neoplasm. It is hoped that these concepts may also be applied in studying neoplasms of other tissues as well.

In the light of present knowledge, our understanding as to the mechanisms through which the thyroid hormone exerts its actions on the cells of the body is a void. Recent studies, however, indicate that tracing labelled thyroid hormone through its circuit may throw some light on the mode of action of this hormone. Gross and LeBlond (47) have observed that thyroxine labelled with I^{131} when administered to intact rats is withdrawn from the blood stream and is demonstrable in various tissues within two hours of its administration. They also observed that it is broken down within the body to diiodotyrosine and iodide. Hamilton, 1948 (48) and Keating and Albert (49) have observed the fate of radio iodine labelled thyroxine, thyroglobulin and iodinated casein in myxedematous patients. They have observed that less than 5 per cent of the labelled iodine is excreted in the feces and that the rest is excreted in the urine. They have found that more than 90 per cent of the labelled iodine excreted in the urine is excreted as iodide and that the remainder is excreted as diiodotyrosine. One might suggest on the basis of these studies that the thyroid hormone in the process of exerting its action is broken down and the iodine liberated to be excreted or utilized in the synthesis of thyroid hormone. It is to be hoped that these studies are only the beginning of investigations which may elucidate the mode of action of the thyroid hormone.

SUMMARY

1. Studies with radioactive iodine have resulted in major contributions to our knowledge of thyroid physiology, normal and morbid.

2. Thus far the completed studies are in harmony with previous observations made with the conventional biochemical techniques. However, because of the fact that with these techniques, physiologic levels of study never before obtained are possible, we have been able to broaden our knowledge of thyroid disease at a level which could not otherwise be reached.

3. With these techniques we have been provided with better concepts as to

- a. the actions of certain thyroid stimulators and inhibitors,
- b. the function and biology of benign and malignant neoplasms of the thyroid,
- c. a possible mode of action of the thyroid hormone on the tissues of the body.

4. It is suggested that these studies are only the beginning of new and intensive investigations on normal and morbid physiology of the thyroid which will not only lead to better understanding of thyroid disease but may also result in more intelligent and physiologic therapy of these maladies.

THE USE OF RADIOIODINE IN PHYSIOLOGICAL AND CLINICAL STUDIES ON THE THYROID GLAND

BY M. S. RABEN¹ AND E. B. ASTWOOD

(From the Joseph H. Pratt Diagnostic Hospital and the Department of Medicine, Tufts Medical School, Boston, Mass.)

The presence of iodine within the molecule of thyroid hormone has greatly facilitated physiological studies on the thyroid gland. In a sense the primary function of the thyroid gland is to regulate the intermediary metabolism of iodine; studies on the fate of iodine in the body, then, bear directly on thyroid physiology. Chemical methods for the detection and quantitative determination of iodine have been developed to a high degree of sensitivity and accuracy, and there are few substances that can be measured by chemical means in such small quantities. The use of radioiodine has not only simplified many procedures which would be most difficult by chemical methods, but it has made it possible to carry out studies which could not have been done by any other means.

First described by Fermi in 1934 (1) radioiodine (I^{128}) was first used in physiological studies by Hertz, Roberts, and Evans in 1938 (2). The longer lived isotopes, I^{130} and I^{131} , more suitable for physiological and clinical experiments, could be produced in limited quantity in the cyclotron and were used in several centers for fundamental investigations. Extensive applications of radioiodine have been possible since 1946 when I^{131} was made in quantity by the chain-reacting uranium pile.

Evidence for physiological identity of radioiodine and I^{127}

By analogy with the isotopes of other elements it was to be expected that radioactive iodine would not differ chemically or in physiological reaction from ordinary iodine. No single experiment with radioiodine establishes this fact, but many observations are consistent with the chemical identity of the several isotopes; no evidence has yet been brought forward to indicate that chemical differences exist. Favoring the supposition that

I^{131} is identical with I^{127} in chemical and physiological reactions are the observations that: (1) under appropriate conditions exchanges to theoretical equilibrium can be observed between radioiodide and diiodotyrosine and vice versa (3); (2) various radioiodine-labelled compounds can be purified to constant specific activity; (3) when physiological experiments are performed using radioactive and chemical methods for iodine in parallel, good agreement is observed; and (4) administered radioactive iodine appears in diiodotyrosine, thyroxine, and protein-bound iodine.

A question which seems not to have been answered, however, concerns the chemical state of the carrier-free iodine which is used in tracer studies. One wonders whether the equilibria which obtain with chemically detectable concentrations of iodine still hold in solutions of almost infinite dilution, and whether one can safely manipulate solutions of carrier-free I^{131} without fear of unpredictable changes in chemical state. The preparation of this material for administration to man or animal must surely carry the hazard of a partial conversion to hypoiodite or even iodate; and, were this to occur, bizarre results might follow, especially after parenteral use. For these and other reasons the use of carrier would seem advisable whenever there is no contraindication to it.

Similar uncertainties may arise when tissues or body fluids containing radioiodine are subjected to chemical procedures. When carrier cannot be used as in the identification of a new or unknown compound, large errors might enter because of the extreme smallness of the quantities involved.

Considerable debate has concerned the extent to which exchange reactions might complicate physiological studies and thus invalidate conclusions. Leblond and Süe (4) found little or no exchange *in vitro* upon admixing radioiodine and iodate or radioiodine and diiodotyrosine in aqueous solution. Miller *et al.* (3), however,

¹ Atomic Energy Commission Postdoctoral Research Fellow in the Medical Sciences of the National Research Council.

have defined certain *in vitro* conditions which are favorable for the exchange between the iodine atoms of diiodotyrosine and iodide or iodine. The reaction is rapid in acid solutions and is accelerated by heat and by oxidative environments which would permit the presence of iodine. At physiological hydrogen ion concentrations, little exchange occurs, and reducing agents are strongly inhibitory. Evidence against the occurrence of simple exchange *in vivo*, as well as against it taking place during the usual *in vitro* fractionation procedures on thyroid tissue, has been provided by the experiments of Morton and Chaikoff (5). They showed that although radioiodine was incorporated into diiodotyrosine and thyroxine by surviving thyroid slices, little or no radioiodine entered these compounds when homogenized thyroid tissue was used.

Absorption, distribution, and excretion of iodide ion

It is usually assumed that iodide ion resembles chloride ion in the rate and extent of its absorption from the intestinal tract and in its distribution in the body fluids. It appears to remain in the extracellular space and to be distributed in the body in a manner which is very similar to chloride and thiocyanate (6). Apparently iodide ion is handled somewhat differently from chloride by the gastric mucosa and the kidney, and, of course, the difference is striking in the case of the thyroid gland. Davenport (7) found that iodide is selectively excreted by the stomach provided the blood concentration is low. As the normal concentration is very low, one would have anticipated that tracer doses of I^{131} would be selectively excreted into the stomach. This has proved to be the case (8), and it is a common observation that shortly after the administration of radioiodine a significantly higher concentration is detectable in the stomach than in other sites, excepting the thyroid and the urine. Marinelli and Hill (9) have calculated that when large doses of I^{131} are given for the treatment of thyroid tumors, the gastric mucosa receives a large dosage of radiation, even when the radioiodine is given intravenously. A temporary decrease in both gastric and salivary secretion has been noted under these circumstances (10). The kidney, at least in some species, excretes iodide

more rapidly than chloride or bromide, and the rate of excretion has been observed to be hastened somewhat by the administration of increased amounts of chloride. This has been strikingly demonstrated recently in the dog. Riggs (11) observed that this species excreted iodide very slowly but that the rate of excretion was greatly enhanced by large amounts of either bromide or chloride, and even by large amounts of iodide.

The renal excretion of a tracer dose of I^{131} in man has been extensively investigated. When a large quantity of iodide labelled with radioiodine is given, virtually all of it can be recovered in the urine within a few days. With small doses or tracer amounts only a fraction appears in the urine, a varying proportion entering the thyroid in firm combination with protein. Hamilton and Soley (12) found that 53 to 81 per cent of a 14 mg. dose was excreted in the urine by normal persons in 24 hours, while a larger fraction was excreted at a somewhat slower rate by individuals with myxedema. Hertz, Roberts, and Salter (13) found that less radioiodine appeared in the urine in cases of hyperthyroidism, a larger proportion being held in the thyroid gland. Again large doses of carrier favored the excretion of a larger proportion of the administered radioiodine. When 2 mg. of carrier or less was used in 11 thyrotoxic individuals, only 10 to 56 per cent of the dose could be recovered in the urine. It developed, therefore, that the proportion of a small dose or a tracer dose of iodine excreted in the urine bore an inverse relation to that taken into the thyroid gland. Several workers have used this phenomenon to study thyroid function in man in preference to direct measurements on the thyroid gland (see below).

Iodide ion can also be detected in other body secretions including saliva, tears, sweat, and milk, and it enters serous effusions and the cerebrospinal fluid (14). Radioiodine has not been used extensively to check these observations, but it can readily be detected in the saliva after it is given by mouth or by injection (8), and it has been found to enter the cerebrospinal fluid slowly.

Concentration of iodide ion by the thyroid

Earlier work with I^{127} showed clearly that the thyroid is capable of accumulating iodine at a rapid rate and that this iodine is quickly bound

to protein (15). Tracer studies with radioiodine have established that two steps are involved in this process: (1) The accumulation of iodide ion, and (2) the organic binding of iodine. It has long been known that a small amount of inorganic iodide can be detected in the normal thyroid gland and that considerable amounts may be found after iodine therapy. Large amounts of inorganic iodide are concentrated in the thyroid in hyperthyroidism after the administration of therapeutic quantities of potassium iodide (16). Lein (17) demonstrated in rabbits, given 35 μ g. of iodide labelled with radioiodine, a prompt accumulation of inorganic iodide followed by a slow accumulation of iodine in a protein-bound form. A still clearer demonstration of the two separate mechanisms involved in iodine collection by the thyroid was given by Franklin and Chaikoff in 1944 (18). It was observed that while sulfonamides inhibited the incorporation of I^{131} into diiodotyrosine and thyroxine by tissue slices *in vitro*, these compounds did not prevent the accumulation of the I^{131} by the slices. McGinty (19) found in rats that, though the organic binding of iodine is completely inhibited by thiouracil feeding, the quantity of iodine in the thyroid gland can be increased by adding potassium iodide to the diet. This iodine, however, was not precipitable with protein and, therefore, presumably still in an inorganic form. It was also noted (20) that the thyroids of rats depleted of iodine by thiouracil treatment would rapidly accumulate iodine if a relatively large dose of ordinary iodide were injected; this freshly accumulated iodine was found to be unattached to protein. Further studies on the iodide ion-concentrating mechanism were greatly facilitated by the finding that it is specifically inhibited by thiocyanate.

It had been noted by Barker (21) that potassium thiocyanate could give rise to goiter and signs of myxedema in man, and it was later found to be goitrogenic in rats (22). However, thiocyanate differed from antithyroid compounds in that its goitrogenic effect could be abolished by increasing the iodide intake. Franklin, Chaikoff, and Lerner (23, 24), using radioiodine, and VanderLaan and Bissell (25), employing ordinary chemical methods, clearly established the effectiveness of thiocyanate in inhibiting the uptake mechanism for iodide. In a detailed study of this

phenomenon VanderLaan and VanderLaan (26) established, as far as current physical and chemical methods would permit, that the iodine accumulated by the thyroid gland, when organic binding is completely inhibited by propylthiouracil, is indeed iodide ion. They showed that thyroid tissue can maintain an iodide ion concentration much higher than that of the circulating blood. This gradient, or, expressed another way, the thyroid/blood iodide ratio, is increased when the thyroid is hyperplastic. Thiocyanate inhibits this concentrating mechanism and within an hour or less after thiocyanate is given, the thyroid/blood iodide ratio has approached 1/1. It is of interest to note that VanderLaan and Vander-

FIG. 1. THE EFFECT IN NORMAL YOUNG RATS OF VARIOUS DOSES OF POTASSIUM THIOCYANATE ON THE THYROID/BLOOD IODIDE RATIO

The animals were injected with 5 mg. of propylthiouracil to prevent organic binding of iodine and were given carrier-free radioiodine two hours, and the potassium thiocyanate one hour before being killed.

Laan found that the use of chemical methods yielded the same results as did radioiodine techniques. The effect on the thyroid/blood ratio of increasing doses of KSCN is shown in Figure 1.

In addition to thiocyanate ion, cyanide and sulfide ions were found by Schachner, Franklin, and Chaikoff (27) to inhibit iodine uptake by thyroid slices *in vitro*. Neither azide, sulfanilamide (27), methylcyanide, or thiourea derivatives (23) inhibited uptake, whereas azide, thioureas, and various aminobenzene derivatives (28)

inhibited the incorporation of the radioiodine into diiodotyrosine and thyroxine.

In the intact animal thiocyanate is the only agent which has thus far been found to inhibit the iodide-concentrating mechanism. Bromide is without effect even when given in large amounts to rat (26) or to man (29). Potassium cyanide, in the small doses tolerated, was ineffective in rats (30).

Quantitative studies in the rat showed that the thyroid/blood iodide ratio averaged 25 in the normal animal and 250 in animals whose thyroids were made hyperplastic by the administration of propylthiouracil (26). Taurog, Chaikoff, and Feller (31) also found values averaging 250 for rats with hyperplastic thyroids and noted that this did not change appreciably over the course of 24 hours following the administration of the tracer dose. Though the calculation may be somewhat in error, it is of interest to note that the values found by Franklin and Chaikoff (18) for iodide uptake in slices of normal sheep thyroid glands bathed in Ringer's solution containing sulfanilamide (cited above) permit one to estimate that the slice/fluid iodide ratio was about 40. By a different method, Wolff and Chaikoff (32) found the thyroid/blood iodide ratio of normal rats to vary between 100 and 290—a value much higher than that given by VanderLaan and VanderLaan. This possibly indicates that the thyroids were somewhat hyperplastic as a consequence of a low iodine intake; though the actual intake was not mentioned in this particular report, other papers from the same laboratory cite the value 0.1 $\mu\text{g.}$ of iodine per gram for the diet usually employed (33). Most laboratory diets contain considerably more iodine than this and animals fed on them would have thyroids in a more nearly "resting" state. Subsequent studies in both man and rat indicate that the iodide gradient is an index of the "activity" of the thyroid. The gradient has been observed to fall rapidly after hypophysectomy and to be increased by thyrotropin (34).

Though thyroid tissue can maintain a high iodide gradient, there is a limit to the total quantity of iodide that it can contain. Appreciable additions can be made to the iodide content of the blood without altering the thyroid/blood ratio, but beyond a critical concentration the ratio progres-

sively falls as the blood concentration is further increased. Taurog, Chaikoff, and Feller (31) found the ratio to be unchanged when 2 $\mu\text{g.}$ or 100 $\mu\text{g.}$ of iodide were given to adult rats. VanderLaan and VanderLaan (26) gave increasing doses of carrier labelled with I^{131} to young rats. No change in the iodide gradient resulted from doses up to 100 $\mu\text{g.}$ of potassium iodide; 300 $\mu\text{g.}$ reduced the ratio to half, and 1000 $\mu\text{g.}$ to less than 1/10 the control ratio. The concentrating mechanism could not be completely saturated, however, and even when 10 mg. were given, the thyroid held more iodide than an equal volume of serum.

Organic binding and hormone synthesis

Iodine compounds in the thyroid. Harington has stated that all the organic iodine in the thyroid can be accounted for in two compounds, diiodotyrosine and thyroxine, basing this conclusion on the results of a series of fractionations of the iodine compounds after alkaline hydrolysis of thyroid gland tissue in progressively stronger alkali (35). These compounds are believed to be present in the gland in peptide linkage as part of a large protein molecule, thyroglobulin, and are neither dialyzable nor directly extractable with butyl alcohol. It has recently been found that a small amount of free thyroxine can be extracted from the rat thyroid gland (36).

About 25 to 30 per cent of the organic iodine in the gland is believed to be in the thyroxine fraction, and in a study of 11 different vertebrates (37), the values were remarkably constant, ranging from 24 to 32 per cent.

If the recent claims of Fink and Fink (38) are correct, however, a radical revision of Harington's thesis would be necessary. Hydrolysis products of thyroid tissue after I^{131} administration were studied by paper partition chromatography. Initially, several radioactive spots were noted which could not be attributed to the known iodine compounds of the thyroid (39), and more recently, both in man and in the rat, the radioactivity in a spot on the paper chromatogram, identified as being due to monoiodotyrosine, was found to be $\frac{1}{3}$ to $\frac{2}{3}$ as intense as that of the diiodotyrosine spot (38).

The iodination mechanism, by which the peptide-linked tyrosyl radicals are iodinated, is

but poorly understood. It is likely that the iodide ion which has entered the gland, and presumably the follicular cell, must be oxidized to I_2 or to IO^- for the iodination to proceed; an oxidative mechanism capable of effecting this step must be sought. A peroxidase enzyme would be a logical possibility, as it would meet the requirements of the high potential involved in the oxidation process. Histochemical evidence of peroxidase activity within the parenchymal cells has been offered by Dempsey (40), challenged by Glock (41), and supported by de Robertis and Grasso (42). It is an attractive hypothesis that H_2O_2 catalyzed by peroxidase converts I^- to I_2 . But the presence of H_2O_2 has yet to be shown, and for that matter, I_2 or IO^- exists in the cell in theory only, or at any rate, has never been chemically identified. The actual persistence of iodine in a tissue cell in either of these forms is highly unlikely, and the transition from iodide through an oxidized form to its incorporation in the benzene ring of tyrosine may occur almost as a single step. In a study of the kinetics of the *in vitro* iodination of tyrosine, Li (43) concluded that, after entrance of the first iodine atom, the second combines immediately. If this process simulates the events in the thyroid gland, the presence of the large amounts of monoiodotyrosine reported by Fink and Fink (38) would be difficult to understand.

Conjugation. A number of facts lend support to the theory proposed by Harington and Barger (44) that diiodotyrosine is the precursor of thyroxine in the thyroid gland. Diiodotyrosine incubated at slightly alkaline pH will be partially converted to thyroxine (45); the iodination of casein gives a high yield of diiodotyrosine and later, after incubation, large amounts of thyroxine can be isolated (46, 47). Observations on the changes with time of the relative specific activities of thyroxine and diiodotyrosine in animals injected with radioactive iodine have yielded results consistent with formulae predicting the relationship of the activities of a substance and its precursor (48).

The formation of thyroxine is thought to occur as the result of the oxidative coupling of two molecules of diiodotyrosine with the elimination of one side chain. The oxidative conditions required for this coupling could potentially be provided by iodine or hypoiodite, or perhaps by what-

ever mechanism produces the oxidation of iodide. It has been pointed out (49) that peroxidase could catalyze this oxidative coupling, but whether a specific enzyme is actually concerned with this step is not known.

The rate at which organic binding and coupling goes on depends on the state of activity of the gland, and is accelerated by thyrotropin (50) and exposure to cold (51), slowed by hypophysectomy (4, 52), and influenced by the *previous* iodide level (36). The rate is also affected by the iodide concentration at any moment (32), as noted below.

An interesting chemical model of the iodination process has been devised by Keston (53). I^{131} in iodide form added to unpasteurized milk failed to yield diiodotyrosine or thyroxine to any considerable extent until xanthine was added to the system, after which 67 per cent of the radioactive iodine could be recovered in these compounds. It is presumed that the xanthine oxidase present in milk liberated H_2O_2 , which either directly, or catalyzed by the peroxidase also present in milk, oxidized the iodide to a more reactive form, which in turn iodinated tyrosyl groups. The enhancing effect of xanthine could be prevented by the addition of thiourea.

Experiments in general demonstrating that the iodination of casein (with elemental iodine) produces diiodotyrosine and thyroxine within the protein make plausible the belief that the process takes place in the thyroid gland at the level of protein molecules. Indeed, diiodotyrosine and thyroxine are formed much more rapidly *in vitro* when protein is iodinated than when the process is carried out with the free amino acid, tyrosine (45, 48).

Extra-thyroidal hormone formation has been suggested by several investigators. If radioactively labelled iodide is injected into thyroidectomized rats, small amounts of the iodine can be recovered in the various tissues of the body as diiodotyrosine and thyroxine (54). The subcutaneous injection of elemental iodine will exert thyroid hormone-like effects (55) and produce considerable iodination of tissue protein (56), but this represents a highly unphysiological situation. The metamorphosis of thyroidectomized amphibians has been found to be stimulated by iodine (57), and the metabolic rates and body weights of thyroidectomized rats have been shown to be slightly

higher on a diet adequate in iodine than on an iodine-deficient diet (58).

The production of cretinism and myxedema by removal of the thyroid, however, would seem to be adequate evidence that if extra-thyroidal production of thyroxine occurs, the quantity falls far below the requirements of the body.

Action of antithyroid compounds. It has been well established by non-radioactive technics that antithyroid compounds of both the thiocarbonamide (thiourea derivatives, etc.) and the aminobenzene (sulfonamides, etc.) types act by inhibiting the formation of thyroid hormone. Numerous studies employing radioactive iodine have confirmed this. Both in tissue slices (18, 23, 28) and in the intact animal (30, 31, 59-62), these substances interfere with the organic binding of iodine, but do not inhibit the thyroid's capacity for concentrating iodide ion. When antithyroid compounds are present in effective concentrations, the incorporation of radioactive iodine into diiodotyrosine and thyroxine is prevented. The first step in hormone synthesis, the iodination of tyrosine, must, therefore, be blocked. In the face of this block, it becomes more difficult to determine whether the second step, the conversion of diiodotyrosine to thyroxine, is also affected, and in fact, it is not really known whether antithyroid compounds influence the latter process. Recently Pitt-Rivers (63) has been able to inhibit the *in vitro* conversion of acetyldiiodotyrosine to acetylthyroxine with a number of antithyroid compounds of both the thiocarbonamide and aminobenzene type (but with amounts of these substances which would probably represent enormous *in vivo* doses).

It has been observed repeatedly that following a single dose of thiouracil (or one of its relatives), or following a prolonged period of administration as well, the resumption of organic binding occurs within a matter of hours after the drug has been stopped (64, 65). If the administration has been continued long enough, a diminution of circulating thyroxine will occur, and an excessive output of thyrotropic hormone by the pituitary gland will have resulted (66, 67). The thyroid gland, under these circumstances, is found to be grossly enlarged, hyperplastic microscopically, and hyperactive as judged by the increased capacity to concentrate radioactive iodide (26). One experi-

ment (68) has suggested a prolonged suppression of the capacity of the rat thyroid to bind radioiodine after a period of thiouracil administration. The turnover rate could, however, have been so fast that the single determination obtained in 48 hours would not necessarily have been conclusive.

A number of possible explanations have been suggested to account for the inhibition of the organic binding of iodine by antithyroid drugs: (1) Thiouracil immediately reduces I_2 *in vitro* at neutral pH, and probably, in this way, inhibits the iodination of casein (69). It could conceivably act in the thyroid either by preventing the oxidation of iodide, or by reducing the oxidation product as rapidly as it is formed. (2) Thiouracil is said to suppress the activity of the peroxidase in the follicular cell (40); and, thus, if this theory of the oxidation mechanism is correct, might act by inhibiting the catalyst of the oxidation, or by serving as a competitive substrate for peroxidase (70). (3) It has been suggested that antithyroid compounds might act by inhibiting the cytochrome-oxidase system (71). The failure of antithyroid compounds to depress thyroid tissue respiration (72), however, makes this possibility remote.

It would seem unlikely, too, that cytochrome-oxidase, or any enzyme which is so widely distributed in the body, should catalyze the oxidation of iodide in the thyroid gland, and not catalyze it in all other tissues as well. We do not, however, know to what factor the thyroid owes its remarkable powers for iodinating proteins. Does a specific oxidative enzyme in the thyroid cell endow it with this property, or does it rather contain only the oxidative potentialities of all cells, but gain its special property through a unique permeability to the iodide ion?

Inhibitory effect of iodide. An observation important to the understanding of the influence of iodine upon the function of the thyroid gland is the striking inhibitory effect of a high concentration of iodide upon the process of organic binding. First demonstrated in 1944 by Morton, Chaikoff, and Rosenfeld (73) for sheep tissue slices bathed with a bicarbonate-Ringer's solution containing varying concentrations of labelled iodide, this phenomenon was later more extensively investigated in intact animals by Wolff and Chaikoff (32, 74). Rats were injected with labelled iodide in doses ranging from 10 to 500 μ g. and the amount

of iodine organically bound calculated from the amount of radioactivity measured in the trichloroacetic acid-precipitable fraction of the thyroid glands. When correlated with the plasma iodide concentration, it was clearly demonstrated that at plasma values above 20 to 35 $\mu\text{g. per cent}$ the organic binding of iodine practically ceased (Figures 2a and 2b). This inhibition could be prolonged for 40 hours from a single, large injection in nephrectomized rats (75).

Recent observations which we have made (76) suggest that, as might have been anticipated, the blocking effect of iodide correlates more directly with the concentration of the ion in the thyroid gland than with the plasma concentration. Evidence for this was obtained from the following findings: (1) The rats used in the experiments of Wolff and Chaikoff (32) maintained an exceed-

ingly high thyroid-serum iodide ratio, probably due to a low dietary iodine intake. Using rats which maintained a lower ratio, we found that considerably greater amounts of iodide were required to cause inhibition of organic binding. (2) If rats injected with a blocking dose of potassium iodide were also given a dose of potassium thiocyanate, which, as indicated earlier, would lower the thyroid-serum ratio, it was found that organic binding could then occur. Under these circumstances, the thyroid iodide concentration had been lowered without changing appreciably the high plasma values.

One is tempted to apply this newer information concerning iodine influence on thyroid function to explain the well-known salutary effect of iodine in Graves' disease. In this condition, when untreated, the gland is enlarged and markedly hyperemic; the parenchymal cells are columnar and tall; the follicles are irregular with many papillary projections into the lumina, which are considerably smaller than normal. The colloid appears decreased in amount, is more liquid than the usual consistency, and the organic iodine concentration of the gland is markedly diminished. Under treatment with iodine (in amounts which are distinctly pharmacological rather than physiological), improvement in clinical signs and symptoms frequently ensues, and local changes occur in the thyroid that might reasonably be described as "involutional." The hyperemia diminishes, the follicular cells become flattened, the follicle is rounded, and its colloid content appears increased. In addition, the organic iodine concentration is greatly increased.

Wolff and Chaikoff (32) have regarded the blocking effect of iodide as a "homeostatic regulator" by means of which "the formation of toxic amounts of thyroid hormone is prevented" and believe further that this mechanism explains in part, at least, the beneficial effect of iodine in Graves' disease. To involve this mechanism alone, would, of course, leave unexplained the fact that the organic iodine content of the thyroid, both in the normal animal and in Graves' disease, increases with iodine therapy. It is interesting to note that the data presented by Chaikoff and co-workers (32, 73) demonstrate, though it is not pointed out by the authors, that below the iodide concentration values necessary for inhibition, the absolute

FIGS. 2a and 2b. IODIDE INHIBITION OF ORGANIC BINDING

Groups of rats injected with 10 $\mu\text{g.}$ (Figure 2a) and 200 $\mu\text{g.}$ (Figure 2b) of iodide, respectively, as potassium iodide labelled with I^{131} . Inhibition of organic binding (dotted line) persisted until the plasma iodide level fell to about 20.0 $\mu\text{g. per cent}$ (from Wolff and Chaikoff [32]).

amounts of iodine organically bound increase with increasing amounts of iodide present. This phenomenon has also been observed by us in the rat (76) and by Stanley (77) in man. This point would also be consistent with older observations (33, 78) that the organic iodine content of animal thyroids increases with increasing dietary iodine intake, and that intermittent iodine therapy may increase thyrotoxicity (79).

The rapid inhibition of organic binding by a large concentration of iodide is perhaps the best single piece of evidence of a direct effect of iodine upon the function of the thyroid gland. Though it may be argued that an action through the inhibition of thyrotropin has not been ruled out, the site of inhibition would, in any case, have been defined. The influence of iodine upon the size, and both gross and microscopic appearance of the thyroid treated with thiouracil (19, 80), and upon the gland in hyperthyroidism, further suggests a direct effect.

In the reverse situation, in which stimulation of the thyroid occurs as a result of iodine deficiency, it is difficult to know whether the lack of iodine *per se* acts as a stimulus to the gland, or whether this phenomenon is entirely secondary to increased pituitary stimulation.

Studies using the radioautographic technic were first made on thyroid tissue by Hamilton, Soley, and Eichorn (81) in 1940, in experiments which revealed increased radioactivity in hyperplasia and an absence of activity in the thyroid cancer tissue studied. Subsequent studies have confirmed the idea that information about the formation and storage of organic iodine compounds could be obtained by this method, and refinements in technic (82-87) have made very detailed observations possible.

By use of radioautographs, the accumulation of radioactive iodine has been shown in the stolon septum in the ascidians, *Styela* and *Ciona*, as well as in *Amphioxus* (88), in the endostyle of the lamprey larva (89), in the thyroid of the parrot fish (90), and in the thyroids of 10 mm. tadpoles (91) and 18-day-old rat embryos (92).

Leblond and Gross have studied the effects of low-iodine diet and hypophysectomy in rats in this manner (36). Whereas the autographs of rats previously maintained on 2.0 μg . of iodine per day showed the major concentration of radioactiv-

ity in the colloid of thyroid glands removed as early as two minutes after the injection of I^{131} , those of rats which had been maintained on a 20.0 μg . per day iodine intake, showed the radioactivity chiefly within the follicular cells one hour after injection, but almost entirely in the colloid 24 hours after injection. In hypophysectomized animals, however, despite a low iodine intake, the radioactivity was largely in the follicular cells as late as 24 hours after the I^{131} was given. Thus, these three groups showed three distinct rates at which the processes of binding and storage were proceeding. It would seem likely from the photographs reproduced that the iodination of protein took place in the follicular cells, after which it was extruded into the lumina of the acini.

It should be remembered in interpreting these autographs that iodide ion and any dialyzable iodine compounds, would be washed out in the fixing and processing of the tissue sections as generally practiced (93), and only radioactive iodine compounds in proteins, or attached to proteins, would be influencing the autograph obtained. In this regard, the failure to obtain autographs from thiouracil-treated rats (94) could be a case in point; this occurred despite a considerable uptake of inorganic radioactive iodine by the glands.

Leblond and Gross (36) also point out that their autographs indicate that all thyroid cells are active at all times and that all the cells in any one follicle are functioning to the same degree, although there may be different degrees of activities in different follicles. In general, the center of the rat thyroid gland appears to be more active than the periphery, and the authors have also noted a correlation between activity estimations by the radioautographic technic and those based on staining reactions.

It has always been somewhat difficult to picture the mechanics by which thyroglobulin is secreted into the colloid by the thyroid cell, and then later resorbed and secreted into the blood stream. By an interesting analogy, Leblond and Gross help to make this process seem more reasonable: "It may be helpful for the understanding of the follicle function to remember its entodermal origin and to venture a comparison with the intestinal epithelium, which secretes protein (enzymes) into the lumen in a direction consistent with the histological polarity of its cells, and at the same

time resorbs from the lumen smaller molecules resulting from digestion (amino acids —). Similarly, the thyroid epithelium secretes a protein (thyroglobulin) into the follicle lumen and at the same time resorbs smaller molecules, probably thyroxine itself" (36).

The function of human thyroid nodules has also been studied by radioautographs (95-97), at times with concomitant chemical and histological studies, as well as quantitative radioactivity measurements (98,99). In the majority of the reported cases, the nodules have been considerably less active than the surrounding thyroid tissue, even in patients with clinical thyrotoxicosis.

Hormone secretion

That the essential molecule of thyroid hormone is thyroxine has been well established since the pioneering work of Kendall (100) and of Harington (44). Injected in pure crystalline form, it produces metabolic effects which no other known substance can, in comparable amounts, effect. But granting that thyroxine is an essential constituent of the thyroid hormone, some workers have believed that the hormone was a peptide or polypeptide containing this essential compound. Harington, by 1944, (101) was satisfied that the peptide concept was no longer necessary. The concept of thyroxine as the hormone *per se* has received further support from the work of Taurog and Chaikoff (102), who showed that almost all the organic iodine in plasma behaves like thyroxine in that it: (1) precipitates with the protein, (2) from which it cannot be dialyzed, (3) but from which it is readily extracted with butyl alcohol, (4) in which it remains after extraction with 4N NaOH — 5 per cent Na_2CO_3 . In addition, when a rat has labelled its plasma organic iodine from a previous injection of I^{131} , the radioactivity follows added thyroxine carrier. The carrier thyroxine may be recrystallized to constant specific activity, and the radioactive portion resembles thyroxine in its distribution between two immiscible solvents.

Separations of plasma protein fractions have indicated that the largest portion of the protein-bound iodine is carried by albumin, while the highest concentration is in the alpha-globulin fraction, and the lowest in the gamma globulin (102, 103).

If we accept thyroxine as the thyroid hormone, however, a paradox results from the repeated ob-

servations that the effectiveness of fed thyroid extract is greater than can be accounted for by its thyroxine content. This conclusion has been reached by experimenters using a variety of criteria for evaluating the hormonal activity, including the effect on the metabolic rate (104), the suppression of pituitary thyrotropin secretion (105), and the influence on metamorphosis of amphibia (106).

"Proteolytic enzyme." How does thyroxine, which is present in the colloid of the thyroid gland as part of the thyroglobulin molecule, reach the blood as free thyroxine? De Robertis (107) has removed colloid from the follicle lumen by microdissection and tested its proteolytic activity on the protein edestin. Proteolysis occurred with an optimal yield at about pH 4, suggesting a cathepsin as the active enzyme in the experiment. The ubiquity and non-specificity of this type of enzyme, however, makes it a somewhat unsatisfying answer to the problem. It is, nonetheless, of considerable interest that pretreatment of the animal with thyrotropin increased the proteolytic activity and that prolonged iodine treatment, and hypophysectomy (108), decreased it. In addition, the enzyme content was found to be elevated in glands from thyrotoxic patients. One wishes that in this work the results of proteolysis without added protein had been presented, since surely there must have been present a sufficient quantity of protein in the form of the natural substrate in the colloid itself.

Protein-bound iodine of the plasma. Taurog and Chaikoff (102), as a result of their finding that the protein-bound iodine is chiefly in the form of thyroxine, have concluded that the thyroid preferentially secretes thyroxine, and that "only a small fraction of the gland's iodine leaves the gland as diiodotyrosine," although perhaps two-thirds of the organic iodine of the thyroid is in the latter form. This assumption is perhaps unnecessary, however, since it has been found repeatedly that diiodotyrosine is rapidly destroyed in the body. Thus, Leblond and Süe (4) discovered that 30 minutes after the injection of 10 mg. of radioactive diiodotyrosine into rats, 97.5 per cent of the radioactivity in the blood was in the form of iodide ion. No comparable rate of destruction of thyroxine has been demonstrated.

In this regard, it is interesting to note, too, that soon after a dose of radioactive iodide is given,

when the radioactivity first appears in the protein-bound iodine, it is predominantly in the diiodotyrosine-like fraction; later, it is chiefly in the thyroxine-like component (50).

Factors influencing the rate of hormone formation and discharge

The rate, for a given plasma iodide level, at which thyroid hormone is formed and discharged is a function of the general level of activity of the gland, as is the iodide-concentrating power. That these processes may go on independently of each other is neatly demonstrated when, in the presence of an antithyroid drug, the power to concentrate iodide and discharge hormone is retained while hormone formation is prevented, while with thiocyanate, hormone formation and discharge can occur, although the iodide-concentrating power has been lost. Hypophysectomy greatly depresses all three processes, whereas thyrotropin raises the general level of activity of the gland. Thus, beginning eight hours after the injection of thyrotropin in man, a striking increase in the thyroid/serum iodide ratio occurs, as demonstrated by simultane-

FIG. 3. THREE SUCCESSIVE TRACER STUDIES WITH RADIOIODINE IN A NORMAL HUMAN SUBJECT WHO HAD TAKEN 5 GRAINS OF THYROID DAILY FOR SEVERAL MONTHS

A single injection of 15 mg. of thyrotropin was given $4\frac{1}{2}$ hours before the first dose of radioiodine; its effect was noticeable toward the end of the first day and was maximal during the first four hours of the second day; the thyroid had returned to its suppressed state by the fourth day (redrawn from Stanley and Astwood [109]).

FIG. 4. INFLUENCE OF THYROTROPIC HORMONE ON THE RATE OF DISCHARGE OF ORGANICALLY BOUND RADIOIODINE BY THE CHICK THYROID

(From Keating, Rawson, Peacock, and Evans [110]).

ous measurements of radioactivity in the anti-thyroid-blocked gland and the serum (109). The rate at which radioactive iodine is incorporated into thyroid organic iodine is markedly hastened by thyrotropin (4, 50) (Figure 3), as is the rate at which radioactivity appears in the protein-bound iodine (50). It is well known that injections of thyrotropin rapidly deplete the organic iodine content of the thyroid of animals, indicating that, under the conditions of the experiments, at least, the rate of iodine binding does not initially keep up with the rapid rate of discharge. Using radioiodine, Keating, Rawson, Peacock, and Evans (110) found that thyrotropin accelerated the loss of protein-bound iodine from the thyroid gland (Figure 4). Other changes after thyrotropin, such as the liquefaction of the colloid and the reduction in colloid in the follicles, are consistent with the concept of increased proteolytic activity.

Many other factors undoubtedly influence the level of activity of the gland, including the dietary iodine intake and environmental temperature. Leblond *et al.* (51) found that rats exposed to an environment at 0°C . have a higher radioiodine uptake than rats at 22° to 26°C . (control T°), and by the goiter-prevention method (111), it can be shown that a greater amount of administered thyroxine is required in a cold, than in a warm environment.

The fate of thyroxine in the body

When radioactive thyroxine, labelled in the 3',5' positions, is injected into rabbits, very little is found in the thyroid, or in the foetus of a pregnant animal, but a considerable amount rapidly appears in the urine, and the iodine content in the bile is 50 times as great as after an equal amount of iodine as iodide ion (112). *dl*-Thyroxine, labelled as in the preceding experiment, has been injected into rats and its distribution at two and 24 hours studied in more than 40 organs and tissues (113). When the dose was 0.8 mg., approximately 25 per cent of the administered thyroxine was destroyed in two hours and 50 per cent in 24 hours, by which time 80 to 95 per cent of the iodine content had been eliminated from the body. The major route of elimination was via the liver and bile, and within 24 hours, 80 per cent of the injected dose was recovered in the feces, to a large extent as thyroxine. A part of this thyroxine came from direct excretion by the gastrointestinal mucosa. About 11 per cent of the iodine was recovered in the urine after this interval as inorganic iodine, while the organic iodine content of the urine was very small. Within two hours of the injection, 50 per cent was found in the gastrointestinal tract (including liver and pancreas), and not more than 2 per cent could be recovered in the entire circulating plasma volume.

These results on the fate of thyroxine in the body apply to large, unphysiological amounts, and much less is known about the normal course of events. After thyroidectomy in rats, it takes three days for the protein-bound iodine to fall to one-third of its initial level (114), suggesting a much slower rate of loss of thyroxine at physiological levels. However, in an experiment in which rat plasma containing labelled protein-bound iodine was injected intravenously into dogs, it was calculated that the protein-bound iodine was completely replaced every four to seven and one-half hours (115).

Radioiodine in clinical investigation and diagnosis

Investigations on animals have been facilitated by the use of radioiodine and many studies which could be done with ordinary iodine were rendered

much less laborious with tracer technics. In clinical studies, however, tracer methods have made it possible to carry out investigations on thyroid function of a kind which was not possible by other methods. Several different technics have been evolved to estimate the rate of iodine utilization by the thyroid gland, and these have aided in the diagnosis of myxedema and hyperthyroidism, and have furthered the study of simple goiter. These methods have also been applied to the study of factors which influence thyroid function in man such as antithyroid compounds, thiocyanate ion, iodide ion, thyroid administration, thyrotropin, and the ingestion of certain foods.

The urinary excretion of a tracer dose has been used as an indirect measure of thyroid activity by making use of the fact that a proportion of the tracer dose which does not appear in the urine is retained in the thyroid gland. Hamilton and Soley (12), and later Hertz, Roberts, and Salter (13), showed that the urinary excretion of radioiodine had diagnostic value. Rawson *et al.* (116) have shown, by this method, that thiouracil treatment permitted the excretion of the major portion of a tracer dose in the urine, while thyrotoxic patients and one patient with a large hyperplastic non-toxic goiter excreted less than one quarter of the administered radioiodine during 48 hours. Measurements on urinary excretion have also proved useful in determining the amount retained when large doses of radioiodine are used in the investigation and treatment of thyroid tumors (117-119) and in the treatment of hyperthyroidism with radioiodine (120, 121).

Despite the difficulties involved, several observers have found the urinary excretion method of considerable value in the diagnosis of hyper- and hypothyroidism. Skanse (122) measured the amount of radioiodine excreted in the urine during the 48 hours after the administration of 100 μ g. of iodide labelled with I^{131} and found that hyperthyroid patients uniformly excreted less than normal individuals. Oshry and Schmidt (123) measured the total quantity of radioiodine excreted during the first 24 hours after a tracer dose. The values observed are shown in Table I.

A detailed study of the rate of urinary excretion of radioiodine by Keating, Power, Berkson, and Haines (124) has permitted an accurate in-

TABLE I

	Skanse (122)		Oshry and Schmidt (123)	
	No. of cases	Range of radioiodine excretion 48 hours	No. of cases	Range of radioiodine excretion 24 hours
Normal	15	52.7 to 84.1	23	42 to 80
Myxedema	6	72.4 to 91.7	10	48 to 93
Hyperthyroid	25	6.2 to 32.3	34	5 to 43

terpretation of the findings obtained by this method; they have shown that, as the blood is cleared of radioiodine by its excretion in the urine and its incorporation into the thyroid gland, the quantity excreted in the urine progressively declines. Consequently, from the quantities excreted in the urine, measured at frequent intervals, the rate of disappearance of radioiodine from the blood can be calculated.

Keating *et al.* made use of the expression,

$$Q = Q_t(1 - e^{-rt}),$$

where Q is the fraction of the tracer dose excreted in the urine in time t ; Q_t the total quantity to be excreted; and r , a constant defining the rate of disappearance of radioiodine from the blood. The disappearance rate, r , was computed, then, from the formula,

$$r = \frac{\log(Q_t - Q)}{t \log e},$$

or as the slope of the straight line plot of $\log(Q_t - Q)$ against t . As Q_t is the fraction to appear in the urine, $1 - Q_t$ would be the fraction retained in the body. Therefore, the urinary excretion rate becomes:

$$Q_t \times r$$

and the rate of disappearance elsewhere, the "collection rate" is:

$$(1 - Q_t) \times r.$$

This last expression is an index of the rate of incorporation of the tracer dose into the thyroid gland (Figure 5).

The validity of these concepts was established by similar calculations made by estimating the blood disappearance rate on the basis of actual measurements on blood samples, and by calculations using measurements of the accumulation of radioiodine by the thyroid gland. It was even possible to use the decreasing radioactivity of the thigh as a measure of the disappearance rate.

In individuals with thyrotoxicosis the disappearance rate may be extremely rapid and these calculations then do not so nicely follow mathematical prediction. Presumably, at least two additional factors complicate the picture here: (1) The thyroid collection rate is not uniform because it is the resultant of two rates, the rate of establishment of iodide ion equilibrium and the rate

of organic binding, and (2) the significant rate of excretion of iodine-containing compounds by the thyroid gland.

A certain proportion of the radioiodine which fails to appear in the urine cannot be accounted for by the amount which is measured in the thyroid gland. In earlier experiments this "unaccounted for" fraction was very large (13), due probably to technical difficulties of measurement. Even with refined technics, however, some 10 to 20 per cent of the dose is not accounted for (125). It would be expected that a certain small fraction of the administered dose would be contained in the intestinal tract, and some of this might be lost in the stools. It is possible that a small fraction would be excreted by the sweat glands. The observations of Keating *et al.* (124) cited above show that when the turnover of iodine by the thyroid is very rapid, a slow excretion of radioiodine continues for some days after the tracer dose is given. Consequently, another fraction of the "unaccounted for" radioiodine could be that which has been secreted by the thyroid in the form of thyroxine and temporarily stored in body tissue. Direct measurements on the quantity of radioiodine in the thyroid gland are probably more accurate than estimates based on urinary excretion and are far simpler to carry out.

Direct measurements of the collection of iodine by the thyroid gland, using appropriate apparatus, is a more convenient and more versatile method for thyroid studies in man. Methods and detecting devices are constantly being improved, but as yet strictly precise, absolute measurements are not possible. However, for most purposes any one of several currently used technics is satisfactory (125-128), and the method of choice depends upon the nature of the study. When it is desired to determine only the total quantity of radioiodine accumulated, a single measurement at 24 to 48 hours after the tracer dose is sufficient; when more detailed information is desired, measurements can be made at frequent intervals. During the early minutes or hours after a tracer dose is given, the radioiodine is distributed throughout the body and provides a diffuse radiation which complicates the measurements on the thyroid gland. The greater the distance between the detector and the gland, the greater is the difficulty of shielding off the radiation from the rest of the body. When this error

is minimized by placing the detector as close to the thyroid as possible, errors due to positioning and to size, location, and shape of the thyroid gland become maximal. These considerations imply that when absolute values are desired, measurements must be made at a distance and preferably at a time when the body in general contains little radioiodine. When the observation of rapid changes, occurring soon after the tracer is given, is more important than information on the number of microcuries in the gland, it may be necessary to sacrifice the added accuracy of distance in favor of the simpler shielding problem of closer placement.

Curves depicting the collection of radioiodine by the thyroid gland resemble those obtained by Keating *et al.* (124) for cumulative urinary excretion. The course of uptake is apparently complex, and no simple mathematical expression is

FIG. 6. THE COURSE OF RADIOIODINE ACCUMULATION IN THE THYROID GLANDS OF THREE NORMAL AND TWO THYROTOXIC INDIVIDUALS

The figure on the right illustrates the approximately linear relationship when the abscissa is a square root scale.

applicable to all individuals. The formulation of Keating *et al.* provides an approximate description of the pattern seen in most normal persons. In other normal persons and in many abnormal individuals the relationship fails to hold. Another approximation (65) which describes the curve of collection during the first part of its length is the simple relationship

$$Q = G\sqrt{T},$$

where Q is the quantity of radioiodine in the thyroid gland at time T ; and G is a rate constant which serves as an index of the rate of uptake. This expression describes the course of uptake quite accurately in normal persons for the first eight or ten hours after the tracer is given. In hyperthyroidism and in certain instances of goiter, when the collection is rapid, deviation from the parabolic curve occurs sooner, and in some instances the curve of uptake bears little resemblance to a parabola. On the other hand, when the rate of collection is slow, the curve of uptake follows the parabolic curve quite closely for as long as 24 hours (Figure 6).

This method of expressing the rate of accumulation suffers the disadvantages of: (1) Incomplete description of the whole process, (2) marked and early deviations in certain cases, and, (3) obscure mathematical significance. It has the advantage, however, of providing a measurement

of rate within an hour or two of the beginning of the tracer study, and it is the only satisfactory method thus far devised which makes it possible to define the accumulation rate early enough to allow studies on extraneous factors which induce rapid changes in the rate of accumulation.

The rate as determined in this way is not proportional to the total accumulation and is less suitable than the latter as a diagnostic method for hyperthyroidism. Either method is suitable when the diagnosis of myxedema is in question. Neither of these methods is entirely reliable for diagnosis, however, as the range of variation in normal individuals overlaps at either end with myxedema and thyrotoxicosis. Erroneously low accumulation rates and low total uptakes follow iodine or thyroid medication, the administration of compounds used for cholecystography, and the installation of iodized oils into the lungs, subarachnoid space, or other body cavities. Rapid rates and large total uptakes within the hyperthyroid range are sometimes seen in apparently normal persons and in some instances of non-toxic goiter. Despite these limitations, the two methods are valuable and frequently provide strong evidence for or against a diagnosis of myxedema or hyperthyroidism.

Werner, Quimby, and Schmidt (129) have extensively investigated the total collection of iodine by the thyroid by direct measurements 24 hours after the tracer dose. The data are shown in Table II from which it may be seen that little

overlap between the normal values and those of hyperthyroids was encountered.

Iodide ion. Radioiodine, used in conjunction with antithyroid compounds, has made it possible to study the iodide ion concentration by the thyroid gland in human beings and the effects thereon of thiocyanate (29). In man, thyroid hyperplasia, as seen in hyperthyroidism and in certain non-toxic goiters of recent development, is associated with a greatly increased capacity of the gland to hold iodide ion and quantitative measurements of this phenomenon have diagnostic value. Potassium thiocyanate given orally in doses of about 1 gram greatly interferes with the ion-concentrating mechanism and virtually all I^{131} present in the gland in ionic form is lost within an hour.

The organic binding of iodine by the thyroid can be completely or very nearly completely inhibited by the administration of effective doses of an antithyroid compound. Mercaptoimidazole has been used for this purpose because of its high activity in man and its prolonged action, and more recently 1-methyl-2-mercaptoimidazole has proved to be convenient because of the small size of the doses that need be given (130). When radioiodine is administered after the thyroid is fully under the influence of such compounds, it serves to label the iodide ion of the body fluids and the thyroid gland. As far as one can tell, this iodide ion does not enter into any chemical reaction in the body and interpretations are, there-

* Compiled from data of Werner, Quimby, and Schmidt (129).

fore, greatly simplified. Within an hour or two after the tracer dose is given, the radioiodine seems to have distributed itself throughout the body's iodide and this state of equilibrium is maintained for as long as detectable quantities of radioiodine remain in the body. The ion is lost from the body almost exclusively through the urine, and, as a certain fraction of what remains is lost during each succeeding interval of time, the rate of loss is an exponential function. Thus, if one plots the log of the blood concentration against elapsed time, a straight line results. Now, as mentioned above, the thyroid gland can steadily maintain a concentration gradient of iodide ion, and equilibrium conditions here are also quickly established. It follows, therefore, that the maximal thyroid content of radioiodide is to be observed within an hour or two of the tracer dose; thereafter the radioiodide in the thyroid gland declines slowly in a regular logarithmic fashion and becomes undetectable in two to four days. Calculations can be made in man of the thyroid/blood iodide ratio, and, while these are subject to considerable error from patient to patient, the calculated ratio remains remarkably constant throughout the course of a

tracer study on any individual. The decline in the thyroid radioiodide parallels closely the decline in blood radioiodine concentration, so that the ratio remains the same for as long as it can be measured, provided, of course, that sufficient antithyroid compound be given to prevent any change in the chemical state of the iodine.

In the diagnosis of hyperthyroidism, tracer studies of the thyroid iodide content have proved to be more reliable than measurements of the total iodine uptake. There is a greater difference between the hyperthyroid gland and the normal gland, and, with the exception of certain hyperplastic non-toxic goiters, there appears to be no overlap of the ranges of normal and hyperthyroid persons. Furthermore, as might have been predicted from the animal experiments cited above, extraneous ordinary iodide has much less influence on the iodide-concentrating mechanism, and doses of potassium iodide up to 10 mg. or more can be given without altering the thyroid radioiodide. The large collection of iodide ion exhibited by the thyroid in hyperthyroidism and by certain non-toxic goiters can be reproduced in normal individuals by the injection of a single, large dose of thyrotropin (109).

FIG. 7

In the presence of a large carrier dose, the curve of radioiodine uptake and discharge represents largely iodide ion. Thus, the radioactivity in the thyroid may be discharged with thiocyanate (dotted line graph). The carrier doses in the above cases are in the range which inhibits organic binding, but are well below the amount required to depress the thyroid/serum iodide ratio.

If further study confirms the finding that a sudden increase in blood iodide inhibits the organic binding of iodine, another and perhaps better method will be provided for measuring the thyroid iodide for diagnostic purposes. In this instance an appropriate dose of carrier iodine would replace the antithyroid compound. For some hours after the administration of 10 mg. or more of labelled potassium iodide, the quantity of radioiodine fixed in the thyroid is very small. However, within an hour or two of such a dose there is a maximal accumulation of iodine which presumably is free iodide ion, as it is readily discharged by a dose of potassium thiocyanate (Figure 7). The quantity of iodide accumulated under these conditions is independent of the dose of carrier iodide within wide limits. One could, therefore, use a constant dose of carrier with the diagnostic radioiodine in a quantity large enough to reduce the proportion that will be organically bound to a very small value and yet not so large as to impose a limit to the concentrating mechanism. Measurements need only to be made until the early maximum is reached, a period of one to three hours. This technic would be essentially that which Hamilton and Soley used in their first experiments in 1940 (126). The method would have the advantage of simplicity and the time required to carry out the test would be reduced to a minimum. One might anticipate that, though a small fraction of the iodide would be bound, this would be so small in comparison to the quantity concentrated as iodide that it would not seriously interfere with the test.

Antithyroid compounds can readily be studied in normal human beings by making use of the $Q = G\sqrt{T}$ relationship (65). Frequent determinations over one to two hours following the oral administration of a tracer dose permits one to calculate the value of G and to plot the course of uptake with some assurance. A test dose of compound is then given and a significant deviation from the predicted course of events can with reasonable certainty be ascribed to the antithyroid compound. This method has given useful information on the relative antithyroid activities of several compounds and has led to the development of agents which are many times more effective in man than is thiouracil. Some information can be

gained, in this way, on the duration of action as well as on the minimal effective dose.

Foods of possible or potential influence on thyroid function have also been tested in this way (131). The technic used was the same as that described above, except that a full meal of a single food was given instead of a dose of antithyroid compound. A number of foods, especially vegetables, were found to have slight effects on the rate of radioiodine collection by the thyroid gland, and some, such as turnips, were strongly inhibitory. These studies led to the isolation and characterization of an active antithyroid compound in turnip, a substance which was found to be widely distributed among the plants of the brassica genus (132).

Thyroid administration has been observed to have no significant effect upon the accumulation of radioiodine by the thyroid gland during the first ten hours following a single dose. A large dose was found to be definitely inhibitory by 24 hours (133), however, and prolonged treatment in normal individuals virtually abolished the uptake of radioiodine (109, 129).

Thyrotropin was likewise without detectable effect until some eight to 14 hours had elapsed after a single injection. Then a marked increase in the rate of uptake was noted and this lasted for several days (Figure 3). The negligible uptake resulting from prolonged administration of thyroid could be restored to normal by an injection of thyrotropin (109).

Means (134), writing in 1948, has stated, in reference to the use of radioactive iodine in the field of research, that he had "at the time of its introduction, predicted that its usefulness in this field would be greater than in that of therapeutics. Now, after an elapse of ten years, it can be said that the usefulness of radioactive iodine in thyroid research has been firmly established."

RADIOIODINE THERAPY IN GRAVES' DISEASE

A REVIEW

By MAYO H. SOLEY¹ AND NADINE FOREMAN²

(From the Department of Medicine, State University of Iowa, College of Medicine, Iowa City)

HISTORICAL

The discovery of radioactive isotopes of iodine by Fermi (1) in 1934 was followed in 1938 by the use of these tagged atoms in studies of the physiology of the thyroid in human and other animals (2, 3). The selective deposition of radioiodine in the thyroid and the known effectiveness of radiation therapy in selected patients with Graves' disease soon led to the use of two radioactive isotopes of iodine in the treatment of thyrotoxicosis: I^{130} with a half-life of 12.6 hours and I^{131} with a half-life of eight days. Hertz and Roberts (4) first used this method of therapy in the spring of 1941. Hamilton and Lawrence (5) treated their first patients in the fall of 1941 and Chapman and Evans (6) took over the work of Hertz and Roberts (7) in 1943. The earliest reports to allow an even tentative appraisal of radioiodine therapy were published by the latter groups of authors in 1946 (6, 7). In 1948, Soley and Miller (8, 9), published their experiences and later in the same year two other groups recorded their results (Haines, Keating, Power, Williams and Kelsey [10]; Werner, Quimby and Schmidt [11, 12, 13]). Prinzmetal and his coworkers (14, 15) and Crile (16) contributed their material in 1949.

PERSONNEL

Radioiodine as a therapeutic agent in Graves' disease is still in the experimental stage and much remains to be learned about its clinical use, its immediate biological effects, and its long-time effects, both upon the thyroid and upon the patient as a whole. Certain skilled personnel are essential to any program dealing with radioiodine since it is a form of radiation therapy. Such a program may be divided into three general phases: radiological, physical and clinical. There can be no doubt but that the very important problems of radiation

dosimetry and biological effects of ionizing radiations should be handled by a radiologist. The technical problems relating to the physical measurements of radiation, to the maintenance and operation of electronic equipment, and monitoring of the laboratory areas are most capably handled by a physicist. As is always true in medicine, it is important to render care to the patient as a whole. In prescribing a relatively new and powerful remedy, the clinician must make frequent and careful appraisals during the course of treatment and in the long term follow-up of treated patients.

RADIATION EFFECTS OF I^{131}

Although no serious toxic effects have been observed as yet in patients receiving I^{131} therapeutically, thyroidal and extrathyroidal changes have been found in experimental animals.

Gorbman (17) gave young mice 3-55 mc. per kg. of I^{131} to study the effects on the thyroid and adjacent tissue. Within the first day the striking effect was periglandular edema with infiltration by lymphocytes, polymorphonuclear and mast cells. Changes in cells of tracheal epithelium were common. At the end of two days with large doses (53 mc. per kg.) the thyroid was an eosinophilic mass with recognizable follicles only in the peripheral parts of the gland. After three days destruction of the thyroid was complete when 50 mc. per kg. were administered and minimal with the lowest dosage. Comparable changes were noted in parathyroids. Over 20 mc. per kg. caused histologic damage to the recurrent laryngeal nerves. At the end of 24 days as little as 3-5 mc. per kg. caused extensive destruction of the thyroid; 18-22 mc. produced complete thyroid destruction. After an interval of 120 days, the thyroid was only a shrunken fibrous band, except in those animals who had received the smallest amounts of I^{131} .

The University of California investigators (8, 9) found extensive but not complete thyroid destruction by the 30th to 40th days in rabbits from the effects of 300 μ c. per kg. with approxi-

mately a 50% decrease in size of the thyroid glands. The thyroid of one dog sacrificed one hundred days after a similar dose showed fibrosis of vessels as well as the glandular tissue. No other tissues of any of these animals showed changes except the renal tubules of one of the rabbits.

Findlay and LeBlond (18) gave 60–80 $\mu\text{c.}$ of I^{131} to rats previously fed low iodine diets and found less marked histologic changes than those reported by Gorbman in his mice treated with 3 mc. per kg. These findings are consistent with the low dosage used.

If a direct comparison could be made between results in animals and in man, from 210 to 3,500 mc. would be required to produce total thyroid and parathyroid destruction in an average adult of 70 kg., or from ten to 175 times the usual maximum dose used in the treatment of Graves' disease. This safety factor is far greater than is usual with most therapeutic agents.

CALCULATION OF I^{131} DOSAGE

The subject of isotope dosimetry has been well covered by Marinelli (19), Quimby (20), and Marinelli, Quimby and Hine (21), the details of which are beyond the scope of this paper. It is of importance, however, to have some concept of the amount of radiation administered during the course of I^{131} therapy. Only then can conclusions be drawn as to the effectiveness of the method and comparisons between groups of patients be made.

I^{131} gives off two kinds of radiation, beta particles with maximum energy of 0.6 MEV (million electron volts) and gamma rays with energies of 0.37 and 0.08 MEV. Beta particles have a maximum range of approximately 2.5 mm. in tissue and most of their energy is thus expended within the thyroid. Gamma rays are more penetrating and produce but little radiation effect within the thyroid gland.

It is both simple and convenient to accept the following formula for the calculation of equivalent roentgens delivered to the thyroid by I^{131} (beta and gamma).

$$\text{Dose e.r.} = \frac{\mu\text{c. administered} \times \text{uptake \%}}{\text{grams of thyroid}} \times \frac{\text{Biol. H.L.}}{8} \times 160 \quad (15)$$

The dosage depends, then, upon the concentration of radioiodine within the thyroid, upon the half-life of the isotope, and upon the rate at which the radioiodine leaves the thyroid (the biological half-life). The figure "160" represents the approximate no. of equivalent roentgens produced when 1 $\mu\text{c.}$ of I^{131} undergoes total decay. The calculation of tissue dosage assumes that the distribution of the isotope within the thyroid is uniform (even though this is not always the case) and that each retained iodine

atom decays completely. The calculation of radiation dosage in this relatively easy way is of practical value even though it may lack absolute precision.

TECHNIQUE OF TREATMENT

I^{131} is administered orally. Single doses have ranged from 1.0 to 20.0 mc. with good therapeutic results with 2.0 to 12.0 mc. It is obvious that the amount of radioiodine taken up by the thyroid rather than the size of the oral dose is the important factor in determining the amount of radiation to the thyroid. Therefore, most workers have attempted to estimate the weight of the goiter, have measured the uptake of radioiodine by the thyroid gland and then have analyzed the therapeutic results in terms of the number of microcuries of radioactive iodine per gram of thyroid tissue. Haines and his coworkers (10) have devised a simple formula for the calculation of a desired dose:

$$\frac{\text{Microcuries desired per gram of tissue} \times \text{Estimated weight of thyroid in grams} \times 100}{\text{per cent of } \text{I}^{131} \text{ tracer collected by thyroid}}$$

This gives the total desired dose in microcuries.

The dose per gram of thyroid in the 83% of patients who have had good therapeutic results has been from 23.0 to 574.0 $\mu\text{c.}$ Werner, Quimby and Schmidt (11) state that doses of 100 $\mu\text{c.}$ per gram or more are generally adequate, since 24 of 27 patients returned to normal with a single dose of this size. However, no absolute rules can be made and the problem of dosage must ultimately fall upon sound clinical judgment rather than upon simplified formulations.

SELECTION OF PATIENTS

Probably because of the relatively short period of experience with radioiodine for therapeutic use the common denominator in the selection of patients seems to be the unquestioned diagnosis of toxic goiter. The Massachusetts General Hospital group prefer to limit their patients to those over 45 years of age since the possibility of late neoplastic change becomes more important in young patients.

Haines, Keating and coworkers (10) decided "to give therapeutic doses of radioiodine only to those persons for whom the risk and difficulties of other methods of treatment appeared to us (them) to be excessive" and included in their series patients with serious heart disease or other complications which added considerably to the surgical risk, and patients who had recurrent exophthalmic goiter, especially if the latter had had multiple resections of the thyroid and unilateral paralysis of a vocal cord or if extremely small amounts of thyroid gland remained. Their pa-

tients represent therefore ones whose disease had proved resistant to other forms of therapy.

Werner, Quimby and Schmidt (13) have selected patients as young as 18 years of age and have included in somewhat less than half of their series patients with hyperthyroidism, recurrent post-operatively, who had been treated with anti-thyroid drugs for some time without satisfactory relief. All but one of their patients had toxic diffuse goiter and none had true hyperophthalmic goiter.

Crile (16) has followed 22 of his 50 patients long enough to report results of radioiodine therapy. Of these 22, ten had toxic nodular and 12 toxic diffuse goiter. His patients with nodular goiter required larger doses and were more difficult to control than his other group. In addition, the nodular goiters did not decrease as readily in size.

The University of California group have used the following criteria in selecting patients for radioiodine therapy: (1) Definite primary hyperthyroidism up to moderately severe degree; (2) thyroid enlargement not much greater than 80 grams; (3) recurrent hyperthyroidism in patients who have had one or more thyroidectomies with or without parathyroid deficiency or recurrent laryngeal palsies and (4) severe exophthalmos when roentgen therapy seems inadvisable because of the large amount of thyroid tissue present. This group has considered certain factors contraindications to radioiodine therapy: (a) the presence of a nodular goiter; (b) extremely large thyroids with or without pressure symptoms; (c) severe thyrotoxicosis with complications since antithyroid drugs and other measures in conjunction with radioiodine probably provide a safer approach than radioiodine alone; (d) pregnancy; and (e) previous treatment with ordinary iodine unless there is adequate uptake of radioiodine by the thyroid. Prinzmetal, Agress, Bergman and Simkin (14, 15) also feel that patients with toxic nodular goiter should not be treated with radioiodine.

In summary, there are no hard and fast rules concerning selection of patients and many of the differences noted by groups of investigators are more apparent than real. Even after prolonged and extensive experience with any therapy in

any disease, there will be legitimate differences of opinion as to the best of several effective methods.

RESULTS OF TREATMENT OF GRAVES' DISEASE WITH RADIOIODINE I^{131}

The earliest published series of cases is that of Hertz and Roberts (7) who used I^{130} , with a half-life of 12.6 hours (see Table I). Chapman, Skanse and Evans (22) have also reported on the treatment of 65 cases of hyperthyroidism with I^{130} and their results are also included in Table I. In their group of 20 cases, Hertz and Roberts (7) followed radioiodine with a course of treatment with ordinary iodine (I^{127}). This was done so that no harm would result to the patient from prolonged thyrotoxicosis should the radioiodine prove ineffective in controlling the disease. It was thought also that the I^{127} might delay the release of radioiodine from the thyroid during treatment. In this respect, their series is not strictly comparable to that of Chapman, Skanse and Evans (22) who used I^{130} only but it appears likely from the published results that the major effects produced in those 20 cases were due to the radioactive

rather than to the inert iodine. Hertz and Roberts (7) reported on an additional nine cases in which I^{130} was not given with therapeutic intent and they, therefore, have been omitted from this series. The disadvantages in the use of I^{130} are the necessity for being near to its place of production (due to short half-life) and the more frequent production of radiation sickness because of rapid delivery of radiation and rapid destruction of thyroid tissue. It should be noted here that radioiodine which is produced by the cyclotron contains a mixture of isotopes, approximately 90% of which is I^{130} and 10% I^{131} ; thus much of the radiation effect could have been from the I^{131} .

When the longer-lived isotopes I^{131} (half-life, eight days) became more generally available, several groups began treating thyrotoxic patients in various parts of the country (8-11, 13-16, 22). A discussion of the use of this isotope is the primary aim of this paper. The results of therapy with I^{131} in some 288 cases are presented in summary form in Table II. It becomes apparent that considerable variation in methods and in results of treatment among the several groups occurs and this fact is worthy of some comment.

Haines, Keating *et al.* (10) at the Mayo Clinic in their treatment of more severe and complicated cases, used relatively large, single doses of I^{131} .

"A result was considered good if the basal metabolic rate was lowered to plus 15% or further and if the clinical evidences indicated that the patient was in a euthyroid state. Results were classified as fair when the severity of hyperthyroidism was markedly reduced by treatment." Twenty-seven of 40 patients had good results according to their criteria, eight were classified as fair results, and five were failures. Seven of 40 cases (17.5%) developed myxedema following treatment. In view of the nature of the patients treated it obviously was better to overshoot than to undershoot the mark in therapy.

Werner, Quimby and Schmidt (13) at Columbia University reported upon the results of treatment of 58 patients with I^{131} with follow-up studies of from four months to over one year (not included in Table II because of incomplete published data). The average total dosage used was from 3 to 4 mc. with 22 of the 58 patients requiring more than a single therapeutic dose. Forty-eight of 56 patients are now in remission, a case success rate of 86%. Two patients have not been followed sufficiently since the last treatment to permit evaluation. Four cases became hypothyroid for a short period of time but recovered. The average time required to reach normal metabolic levels following treatment was three months. Nearly 50% of

their patients represented recurrent hyperthyroidism after operation; they were not considered to be good surgical risks, and, for the most part, had not come into remission with antithyroid drugs or with X-ray therapy.

Sixty-one patients have been treated at the University of California Hospital (8, 9). Each of the patients treated had either primary or recurrent Graves' disease of mild to moderately severe degree. When the percentage uptake of iodine by the thyroid had been determined, it was possible to make an estimate of the probable optimal dosage of iodine needed, since it could be shown that, over a short period of time, the uptake of a large (therapeutic) dose as a rule would be the same as that of a small (tracer) dose. Following treatment, patients were re-evaluated at two to four week intervals and second, third, or fourth treatments were given as necessary. The usual interval between treatments was from four to six weeks. A good result was one in which complete remission of the signs and symptoms of Graves' disease occurred with return of the thyroid to normal size within a reasonable length of time, irrespective of the number of doses required. Of the 61 cases which now have been reported, 51, or 84%, were considered to be good results. The remaining ten patients (16%) were reported as fair results due to the fact that they were under treatment for a long period of time before reaching the euthyroid state. It is apparent that these ten patients represent, on the average, a more severe degree of hyperthyroidism and that larger doses of radioiodine were necessary for the control of their disease. At least a part of the difficulty lay in the fact that $\frac{9}{10}$ of these patients were treated rather early in the course of this study when only limited amounts of iodine were available and when low dosage schedules were being used. Three patients could not be followed or evaluated properly and represent therapeutic failures. The first was a 35 year old woman with severe Graves' disease. She received a total of 4 mc. of I^{131} in two doses, with return to normal thyroid status within two months of the beginning of therapy. Two months later she developed an acute rheumatic pancarditis and it became impossible to appraise her thyroid status accurately. The second case was a 53 year old woman with symptoms and signs of hyperthyroidism, with goiter, elevated BMR and high protein-bound

iodine. She was given a total of 6 mc. of I^{131} without improvement in her clinical condition. She later underwent a subtotal thyroidectomy at another hospital and the thyroid was found to be nodular and fibrotic. The third failure was a woman whose treatment for Graves' disease with radioiodine was interrupted by the development of a major psychotic episode. The latter two patients were not included in the tabulated results.

The 65 cases reported by Chapman, Skanse, and Evans (22) of the Massachusetts General Hospital are quite comparable with those from the University of California. Although the average total dose of radioiodine (in millicuries) exceeds that given the University of California group and was administered as a single dose, the estimated number of microcuries per gram of thyroid is quite similar, as are the results of treatment.³ Fifty-six of the 65 patients experienced good results following I^{131} therapy whereas eight of 65 were improved but not clinically well six months after treatment. Four of their cases developed hypothyroidism but there were no other complications. One of the 65 died of myocardial infarction shortly after treatment and therefore is omitted from the tabulated results.

Crile (16), at the Cleveland Clinic, has treated 50 patients with radioiodine and has reported upon the results in 22 cases who have been followed for from three to ten months. Twelve patients had diffuse toxic goiter and the remaining ten toxic nodular goiter. Eleven of the 12 patients in the first group responded well to treatment, with relief of symptoms of hyperthyroidism and a significant decrease in thyroid size. Only one patient in this group was not classified as a good result even though much improved. Because of the relatively short period of follow-up, it is perhaps not justifiable to class this as a poor result. The patients with toxic nodular goiter have proven considerably more difficult to control by this method of therapy; they require larger doses of radioiodine to produce a remission in their disease, the length of time required to bring about improvement is longer,

³ At the time that these studies were carried out, the millicurie as measured at the University of California apparently was about $2\frac{1}{2}$ times that of the Massachusetts General Hospital; consequently the average total dosage is more nearly the same than would appear from the data.

and the nodular thyroid does not decrease as readily in size. Of ten such cases, only four (40%) have made a clinical recovery while the remaining six are still under treatment. (Results tabulated in Table II.)

Prinzmetal and co-workers (14, 15) have compiled complete data on 44 patients, all of which have been followed for more than one year. Twenty-six were uncomplicated cases of Graves' disease, comparable with those of the University of California group. Using a schedule of multiple, relatively conservative doses, Prinzmetal succeeded in producing satisfactory remissions in 25 of 26 patients within three to four months. The last patient of the group is reported to be improved, but not completely well after one year of study. "Three patients developed hypometabolism and one patient developed signs and symptoms of myxedema. One patient who apparently relapsed had complete return to normal after further iodine administration." The remaining 18 cases presented one or more rather serious complications in addition to their hyperthyroidism. Of the group, 16 (89%) became relieved of their thyrotoxicosis within four months, on the average. One patient did not respond at all and another was improved only moderately.

The overall incidence of clinically good results in the 288 hyperthyroid patients summarized is 83%; 9.7% can be classed as fair results; 5.5% as failures. Results of treatment of toxic nodular goiter with radioiodine have been relatively disappointing since only four out of ten did well.

Some attempt should be made to explain the differences in results obtained in patients when equal quantities of radioiodine are given, and in various series of patients who presumably are handled in the same way. Probably not a great source of discrepancy is the variability of standardization of the iodine at different institutions throughout the country. The major difficulty lies in the calculation of radiation dosage for any given patient. Apart from the factors of physical characteristics of the administered radiation, dosage is dependent upon (1) the percentage which is taken up and held by the thyroid, (2) the size of the gland in which the iodine is distributed, and (3) the rate at which the iodine leaves the thyroid. The greatest source of error is, of course, in the estimation of thyroid size, a subjective error which cannot

readily be measured. Even if it were possible to guess accurately the weight of the thyroid, certain differences in therapeutic results would be observed due to variations in response to a given amount of radiation in individual patients. Hence, as has been reported by several groups (8-13), myxedema may follow relatively small doses of radioiodine (in $\mu\text{c.}$ per gram) while patients receiving much greater amounts do not go below normal metabolic levels.

COMPLICATIONS

Certain phenomena seen within the immediate post-therapy period are worthy of comment but do not constitute true complications. Within the first two to three days, spontaneous tenderness in the thyroid or tenderness on palpation may be noted and this coincides with an increase in the sedimentation rate. This is seen mainly after single doses of two or more millicuries of I^{131} .

Within the first one or two weeks after I^{131} has been administered, some increase in the severity of thyrotoxic symptoms may occur and is associated with a rise in the protein-bound iodine in the blood. Werner, Quimby and Schmidt (11) state that the average increase in the basal metabolic rate in three patients was 15%. The mechanism of the exacerbation probably is rapid radiation destruction of the thyroid and release of stored hormone.

Patients and examiners alike are apt to find that the thyroid becomes firm and even hard within a few days after therapy. This may be associated with a sore throat and cough, the latter persisting for several weeks.

In only one instance has radiation sickness been noted (10), and this was questionable. This is in distinct contrast with the findings of Chapman and Evans (6) who observed radiation sickness in six of 65 patients treated with I^{130} .

Transient hypothyroidism has been seen in four of 58 patients (13), actual hypothyroidism in three of 26 patients (14, 15) and myxedema in 16 of the entire 288 patients treated with I^{131} .

Five deaths occurred among the 288 patients within a period of days to several months following treatment—a remarkable record when one considers the severity of illness of some of the patients treated especially by Prinzmetal's and Haines' groups. Two of the five died of myo-

cardial infarction, two of cerebral-vascular accidents and one of cardiac failure.

Apparently, severe progression of exophthalmos has not been a troublesome feature of radioiodine therapy. Soley, Miller, and Foreman (9) found a progression of 1.5 mm. in 11 of 50 patients and an increase of 3 or more mm. in four of the 50 while none showed a decrease of 1.5 mm. or more. Thus 30% showed a significant increase in the prominence of their eyes. By way of comparison, 26% of 75 hyperthyroid patients who received roentgen-ray therapy had progression of 1.5 mm. or more and 6.6% showed a decrease of the same magnitude. Following subtotal thyroidectomy for Graves' disease, 40-50% of the patients had an increase in the prominence of their eyes of 1.5 mm. or more.

Relapses after probably inadequate therapy have occurred in the experience of all investigators but true recurrences are rare, because the length of follow-up has not been of sufficient duration for recurrence to take place in well-treated patients.

COMPARISON WITH OTHER METHODS OF TREATMENT

Means (23) in 1946 appraised the modern methods of treating Graves' disease but did not have the advantage of recent published work with antithyroid drugs or radioactive iodine. Up to the time of writing this paper, data still are not available to determine precisely the relative merits of (1) preparation of the patient with an antithyroid drug followed by subtotal thyroidectomy, (2) treatment with antithyroid drugs alone, (3) roentgen-ray treatment, and (4) treatment with radioiodine.

These various methods may be evaluated briefly as follows:

(1). In skilled hands with an efficient team, subtotal thyroidectomy in the well-prepared patient who has been on propyl thiouracil or one of the other thiouracil derivatives, carries a mortality of 0.5% or less and is accompanied by the hazards of parathyroid and recurrent laryngeal nerve injury in a small percentage of patients. In addition a varying number of patients will develop myxedema which can be treated readily with thyroid. The recurrence rate is under 5%. Probably more patients can be treated successfully this way than by any single method.

(2). The commonly used thiouracils will in nearly all patients produce a satisfactory remission in Graves' disease. Thiouracil carries the same mortality hazard as subtotal thyroidectomy and in turn produces toxic effects in nearly 15% of patients, the most serious of which is agranulocytosis in approximately 2%. Propyl thiouracil is much safer. However, after six to nine months of full remission, from perhaps 15% to over 50% of people will have a recurrence of hyperthyroidism when the drug is discontinued. The danger of neoplastic changes remains an unknown quantity. Advantages are the simplicity of therapy, the general satisfactory response of the patient and relatively low cost.

(3). Roentgen-ray therapy is not widely employed by thyroidologists, but has given good therapeutic responses in selected patients: those with moderate hyperthyroidism, with non-nodular goiters up to about 60 grams without complications such as coincident heart disease in which a rather slow return to normal might jeopardize the patient and with no history of sun-sensitivity or chronic laryngitis. The chief disadvantage is the comparatively long period required for complete remission. A great advantage is the absence of any mortality from the therapy itself.

(4). Radioiodine can be expected to produce satisfactory remissions in over 80% of patients and many of the other patients would (with less strict criteria than justifiably conservative observers have established) have had reasonably satisfactory end results. The only recorded deaths following I^{131} were not related to the iodine therapy. No serious complications have been noted, but the possibility of late radiation change (tumors) has not been excluded. A disadvantage is the need for technical equipment and skilled personnel beyond that required for other methods of therapy.

Probably the most logical attitude for the therapist in Graves' disease is the recognition of at least four empirical but satisfactory types of treatment, any one of which or combinations of which should be selected for a given patient depending upon individual consideration of the patient and the special skills of the physician.

SUMMARY

An attempt has been made to present the total experience, to date, in the treatment of thyrotoxi-

cosis with radioactive iodine. Although there are differences among various groups in the methods of treatment, the end results are quite similar and compare favorably with already accepted forms of therapy.

The use of radioactive materials in clinical medicine brings with it the necessity for specially trained personnel, and strict attention to the potential hazards of radiation both to patients and to physicians. In this, the relatively young era of isotope application, progress must be made slowly and carefully. It is not unlikely, however, that radioiodine therapy ultimately will come into more general use.

THE UPTAKE AND ELIMINATION OF KRYPTON AND OTHER INERT GASES BY THE HUMAN BODY¹

By C. A. TOBIAS, H. B. JONES, J. H. LAWRENCE, AND J. G. HAMILTON

(From the Divisions of Medical Physics² and Medicine, and the Radiation Laboratory, University of California, Berkeley, California)

INTRODUCTION

Chemically inert gases, such as nitrogen, helium, neon, argon, krypton and xenon, apparently do not participate at normal pressures in biochemical reactions of the human body. These gases are present in physical solution, chiefly in the body water and fat. In recent years much interest has been focused on the exchange of these gases between body fluids and external air, through the lungs, skin and intestinal wall. A number of important physiological processes may be studied by means of inert gas exchange measurements.

During rapid decompression from several atmospheres to one atmosphere or from one atmosphere to a fraction of an atmosphere the dissolved inert gases originally in equilibrium may become relatively supersaturated so that under certain conditions gas bubbles may form in the blood and tissues (1). These may exert mechanical pressure on nerve endings or may cause pain by some other mechanism (2). Our investigations were initiated with the explicit desire to provide (a) classification procedures for selection of high altitude flyers on the basis of gas exchange rates; (b) information on methods of prevention of bends by accelerating the elimination of nitrogen or inert gas or by pre-breathing oxygen. In attempting to solve these two problems, which were of immediate practical importance, we could spend relatively little time on the study of the fundamental mechanisms of inert gas exchange. Answers to the problems *a* and *b* have been given elsewhere (3, 4) and the purpose of this paper is to describe some experiments which pertain to the mechanism of inert gas exchange in the human body.

After Zuntz (5) postulated a mechanism for the exchange of dissolved nitrogen between the tissues and the lungs, Boycott *et al.* (6) carried out experiments on goats and men subjected to excess pressure and determined the general shape of the nitrogen desaturation curve. Bornstein (7) and later Campbell and Hill (8, 9) made further studies of nitrogen exchange, showing that rates of exchange are different in various parts of the body. Shaw *et al.* (10) demonstrated on dogs that under conditions of equilibrium at pressures up to four atmospheres, the nitrogen content of the body is proportional to the partial pressure of nitrogen in the lungs, and that the nitrogen saturation time is the same as the desaturation time. Behnke *et al.* (11-14) also showed that the slope of the nitrogen elimination curve is a function of the cardiac output and suggested that helium exchange is faster, argon exchange slower than that of nitrogen, gas elimination more rapid from the fluid constituents of tissues, and slower from tissues high in fat, and showed that helium and nitrogen may diffuse slowly through the skin. Throughout most of the above described work the whole body elimination was studied more thoroughly than that of specific regions because of lack of suitable methods. Recently Ferris *et al.* (15) measured the nitrogen exchange in man by determining changes in nitrogen content of arterial and venous blood samples. They found that arterial blood reaches equilibrium with pulmonary nitrogen within a few minutes, while venous blood reaches equilibrium much more slowly. Whiteley *et al.* (16) observed the same in the femoral vessels of cats and found that exercise increases the rate of denitrogenation. During the war Smith and Morales also carried out some similar experiments (17-19). The mechanism of total body gas exchange was put on a new basis as a result of work by Jones and his collaborators (20) who demonstrated that diffusion plays very little role in the uptake of various gases by tissues, and that the rapidity of gas exchange depends mainly on the gas carrying power

¹ These investigations were initiated originally through the support of the Columbia Foundation (Columbia Fund for Medical Physics) and subsequently supported through a contract recommended by the Committee on Medical Research between the Office of Scientific Research and Development and the University of California.

of the blood, that is gas solubility in blood and the rate of perfusion of the tissues by blood.

EXPERIMENTAL METHODS

A glance at Table I shows that it is difficult to work with radioactive nitrogen because of its short half life—the gases argon, krypton and xenon are much better suited for tracer investigations. Fortunately it is permissible to use these gases instead of nitrogen if suitable correction factors are applied in interpreting the results. Two kinds of corrections are needed. First one has to take account of the fact that the water and fat solubilities of these gases are different. A detailed analysis of these solubilities by Lawrence *et al.* (21) is summarized in Table II. In addition, another correction factor must be used whenever diffusion of these gases influences the rate of gas exchange. As predicted by Graham's Law, Jones *et al.* recently demonstrated that the noble gases diffuse through gelatin membranes at room temperature at rates which vary inversely with the square root of the molecular weights of the gases.

In the present series of tests the absolute amount of inert gases in the tissues was emphasized less than the relative rate of their uptake and desaturation. Prior to

uptake measurements the radioactive gases were introduced into a closed circuit spirometer. The concentration of gas in the spirometer was determined by a Geiger-Mueller counter. In most experiments this concentration was held constant throughout the period of radioactive gas uptake in the body. In this way the final volume of the spirometer did not enter into consideration when the rate of body uptake was determined. The simple method of measurement required placing a Geiger-Mueller counter against the body region studied and continuously recording the counting rate.³ The schematic setup is shown in Figure 1, Diagram 1a. A counter was held gently in one hand, surrounded by a lead shield, as shown in Figure 1, Diagram 1c, and the left knee was placed on a lead slit, limiting the solid angle of measurement for another counter (Figure 1, Diagram 1b).

Preparation of the radioactive gases in the cyclotron required special techniques. Except in the cases of N^{13} , and A^{41} , halides were bombarded by deuterons; potassium chloride for A^{37} , potassium bromide for $Kr^{81, 79}$ and potassium iodide for Xe^{127} . Because of the high intensity of the deuteron beam, it was necessary to design a target which spread the deuteron beam over a relatively large area so that heat generated could be dissipated. The target plate was tilted so that the effective portion of the beam was spread over an area of 30 square cm. It was also found necessary to isolate the space above the target from the cyclotron vacuum because during bombardment a considerable amount of occluded gas may be released from the target and this would seriously hamper the maintenance of a proper degree of vacuum in the cyclotron as well as cause a loss of the radioactive noble gas formed during the period of exposure. Two thin aluminum windows, cooled by compressed air, were used. The space above the target (the so-called bell jar) was usually filled with He at $\frac{1}{2}$ atmospheric pressure. The target plates themselves were made of $\frac{1}{4}$ inch copper plate with a grooved surface. The halide salts were fused to the reduced surface of the target at a

³ These methods were developed in collaboration with J. B. Mohny and F. W. Loomis of this laboratory.

temperature of approximately 650° C. In addition to potassium, halides of Rb, Sc, Sr and Ba have also been employed with no advantage over potassium salts. Lithium halides are undesirable because of their low melting points and hygroscopic properties, and sodium salts are not used because of the very intense gamma ray activity arising from Na^{24} after bombardment. About 10% of the radioactive inert gases was collected in the bell jar. The remainder is retained in the salt. The bombarded salt is usually scraped off the target plate and fused in a sealed evacuated quartz test tube. The occluded gas is easily driven off at a temperature of 650° C. along with some halogen vapor contamination, usually radioactive (e.g., Br^{80} , 4.4 hours; Br^{82} , 34 hours; I^{129} , 25 minutes). These vapors are absorbed when passing through alkaline sodium sulfide solution. The radioactive inert gas along with some inactive helium and nitrogen is then collected in an evacuated bulb. In most experiments 1-2 cm^3 of carrier gas was added, then the sample was compressed in a suitable bottle with pure oxygen to ~ 250 lbs/sq. inch. Calibration of the radioactivity was accomplished by taking a known volume of mixed gas from the compressed sample and determin-

ing its γ activity in comparing it with a radium standard. During experimental use the gas flow was regulated by a needle valve, and the volume measured by a spirometer (see Figure 1). It is possible to salvage some of the long-life radioactive gases after each experiment for repeated use by collecting the entire expired air during the test, then re-absorbing it in silica gel at liquid air temperature. Recovery of the gases from the silica gel is carried out in the following manner. The silica gel is slowly heated, oxygen, nitrogen, and carbon dioxide are liberated first, followed by radioxenon or krypton. About 60% of the original radioxenon or krypton can be recovered by this method in the last liter of gas given off. Purification processes for somewhat different purposes are also described by Brown *et al.* (22).

The amount of radioactivity necessary for each uptake desaturation experiment was about 0.4 millicurie⁴ and less than half this amount was absorbed in the body.

⁴ Since this work was done, the potential efficiency of gamma ray counting has been greatly increased by the use of fluorescence counters. This will allow the use of smaller radioactive samples in such experiments in the future.

All data were corrected for radioactive decay by multiplying each counting rate by $e^{\lambda t}$ where λ is the decay constant of the radioactive gas used; t is the time elapsed since the beginning of the experiment.

EXPERIMENTAL RESULTS

The relative uptake and desaturation curves of the right hand and left knee were obtained by measuring the rate of gamma ray counts from them in function of time. A typical result obtained in two different experiments on the same person is shown in Figure 2. The counting rate was 3000/minute near the peak of the curve. The experimental points did not fall exactly on the interpolated curves, due to random statistical fluctuations in the number of quanta emitted. If the subject moved during the experiment, other deviations in the measured counting rate occurred. For these reasons exact mathematical analysis of the data is not possible. At the beginning of the uptake experiments there usually was a delay between the time when breathing from the mask started and the time the first traces of radioactive gas appeared in the extremities. The delay amounted to 30 to 90 seconds and was due to the time required for mixing of the gases of alveolar

air and spirometer (20 to 40 seconds half time) and transportation of the blood to the extremities. In searching for a suitable analytical expression for the shape of the uptake and desaturation curves we attempted to divide them into sums of simple exponential functions. The hand data could be satisfactorily approximated by the sum of three exponential functions. Analysis of the knee data makes it appear that the fastest of the three components has a negligible contribution so that the knee data, as well as total uptake data, may be described as the sum of two exponential functions of time. Unfortunately complete saturation of the hands or knees was not reached in the three hours maximum period of the "uptake" experiment. Because of discomfort of the subjects breathing the radioactive gas mixture from the somewhat uncomfortable masks, no attempts were made to follow the uptake longer than three hours. The desaturation, with the subject breathing air in a well ventilated room, was carried out up to 12 hours.

Four subjects participated in two consecutive tests each; in one test they inhaled radiokrypton at a constant concentration for a short period of

FIG. 2. TYPICAL UPTAKE AND DESATURATION EXPERIMENTS WITH RADIOKRYPTON

The concentration of radioactive gas in the spirometer was held constant. The theoretical curves represent the sum of three exponents adjusted to the data as described in the text.

FIG. 3. PLOT OF DESATURATION CURVE ON SEMI-LOGARITHMIC PAPER AFTER SATURATION OF SUBJECT WITH RADIOISOTOPE FOR 20 MINUTES

The three components of desaturation are represented by straight lines.

time (about 30 minutes); the mask was then taken off and desaturation was continued by breathing air. In the second test, uptake was continued for about 120 minutes, followed by desaturation up to 12 hours.

Figure 2 shows the shape of the hand uptake and desaturation curves in two different experiments on the same subject. The uptake Φ in this and other experiments was found to fit the empirical formula:

$$\Phi = A_1(1 - 2^{-(t/T_1)}) + A_2(1 - 2^{-(t/T_2)}) + A_3(1 - 2^{-(t/T_3)})$$

is the sum of three exponential type "saturation" curves. The "amplitudes" of these three components are A_1 , A_2 and A_3 and the "half saturation times" characteristic of the rate of krypton uptake are T_1 , T_2 and T_3 ; while t is the time elapsed after the beginning of the gas uptake. The data are plotted in such a way that

$$A_1 + A_2 + A_3 = 1.$$

The shape of the desaturation curves differs from the saturation curves, inasmuch as the desaturation after 20 minutes uptake does not follow exactly the same law as desaturation after 120 minutes uptake. To obtain some information regarding the analytical shape of the desaturation curves, they were plotted again in Figures 3-5 on semilogarithmic scale. It became clear the desaturation curves Ψ may be expressed approximately as sums of three exponentially decaying functions of the form

$$\Psi(\kappa, \tau) = a_1 2^{-(\tau/T_{d1})} + a_2 2^{-(\tau/T_{d2})} + a_3 2^{-(\tau/T_{d3})}.$$

Here κ is the time taken for saturation; a_1 , a_2 , and a_3 are amplitudes again; τ is the time elapsed since beginning of desaturation; T_{d1} , T_{d2} , T_{d3} are characteristic desaturation half times. The measured values of some of the constants " a_i " and T_{di} are given in Table III. It is found by inspection of Table III, and similar data taken on other subjects, that the values T_{di} are about the same irrespective of the length of time of uptake, while the amplitudes " a " are different for the two different experiments.

Comparing the constants of the uptake and desaturation experiments it was found that within reasonable agreement of the data obtained the constants expressing

FIG. 4. PLOT OF DESATURATION CURVE ON SEMI-LOGARITHMIC PAPER AFTER SATURATION OF SUBJECT WITH RADIOISOTOPE FOR 117 MINUTES

FIG. 5. PLOT OF DESATURATION CURVE ON SEMI-LOGARITHMIC PAPER AFTER COMPLETE SATURATION OF SUBJECT WITH RADIOKRYPTON

the empirical uptake curve and desaturation curve are related. First the half saturation and half desaturation times are about equal

$$\begin{aligned} T_1 &\approx T_{d1}, \\ T_2 &\approx T_{d2}, \\ T_3 &\approx T_{d3}. \end{aligned}$$

Second, the amplitudes "a" of desaturation curves, obtained after saturation for time κ obey the following approximate relationships:

$$\begin{aligned} a_1 &= A_1(1 - 2^{-(\kappa/T_1)}), \\ a_2 &= A_2(1 - 2^{-(\kappa/T_2)}), \\ a_3 &= A_3(1 - 2^{-(\kappa/T_3)}). \end{aligned}$$

Consequently, using the constants obtained in uptake experiments, the empirical formula of desaturation after saturation may be obtained as

$$\Psi(\kappa, \tau) = A_1(1 - 2^{-(\kappa/T_1)})2^{-(\tau/T_1)} + A_2(1 - 2^{-(\kappa/T_2)})2^{-(\tau/T_2)} + A_3(1 - 2^{-(\kappa/T_3)})2^{-(\tau/T_3)}.$$

Data obtained on four different subjects bearing on this point are given in Table IV. Further analysis of the data are possible along the lines of thought of Smith and Morales (17-19) or Tobias (23). These might result in better knowledge of the transport mechanisms involved.

TABLE III

Amplitudes and half desaturation times of the same subject after different saturation times

Half desaturation times τ			Amplitudes a		
	τ after 20 minutes uptake	τ after 117 minutes uptake		After 20 minutes uptake	After 117 minutes uptake
	minutes	minutes			
T_1	6	6	a_1	.48	.23
T_2	39	42	a_2	.49	.675
T_3	310	320	a_3	.03	.095

It would appear then that saturation of the extremities with inert gases is not a strictly reversible phenomenon with desaturation as far as time dependence of the process goes. One may say that it appears as though in the hand there were at least three distinctly different reservoirs containing inert gas; they may be distinguished by the rapidity of the dissolved gas exchange. The filling of these three reservoirs is somewhat independent from each other inasmuch as the time of filling, as characterized by the half saturation time, falls in a definite range. The saturation of each reservoir may be at the present state of experimental accuracy, expressed by a single exponential type function.

r = relatively resistant. s = susceptible. i = intermediate.

Examining the three components in a typical uptake curve one might say that the fastest component probably has something to do with the inert gas exchange between blood and very vascularized tissues. The $\frac{1}{2}$ saturation time (T_1) for this component appears to be ~ two to 10 minutes for the hand. This component of the hand curve accounts in intensity for 2 to 15% of the total radioactive gas content. Its rapidity is in good agreement with the direct findings of Cook and Sears (24) on dogs, and Ferris *et al.* (15) for humans. They find that exchange of inert gases (krypton in dogs, nitrogen in humans) with arterial blood is rapid; one passage of blood through the lungs is enough to empty or fill it with gases to ~ 80 to 95% of the equilibrium value. After a few seconds of transport time the arterial blood enters the hand; in its passage through the capillaries, it uploads most of the radioactive gas to the tissues and returns as venous blood empty of gas to the lungs where it takes up more. The characteristic of this component is its variability in half saturation time, or amplitude; this is to be expected and further data regarding it will be presented below. In the knee region this component may be found only with a very small amplitude: the amount of dissolved gases in blood at the knee region is small compared to the amount dissolved in the water and fat, due to the relatively lesser vascularity.

The second component of the inert krypton uptake has a half saturation time T_2 between 10 and 40-50 minutes in the hand and between 35 and 72 minutes in the knee. The amplitude of this com-

ponent in a group of young persons varies between 50 and 66% of the total for the hand and 17 and 42% in the knee region. If there were no third component, to all practical purposes complete saturation of the hand would be reached in about 90 minutes and 150 minutes in the knee.

The third component for the hand has 100 to 320 minutes half time, with the amplitude between 35 and 55%. T_3 varies between 190 and 870 minutes in the knee with an amplitude variation of 61 to 90%.

Table V shows a set of hand data taken on different subjects and Table VI shows the constants of the knee region taken on seven subjects. In the same tables the susceptibility to decompression sickness is shown, as determined in repeated ascents in the decompression chamber by standard exercise methods. Though gas ex-

change has a bearing on the development of decompression sickness, there is no obvious correlation in the data presented. It has been shown with other methods that total resting nitrogen exchange has correlation to bends, but also that there are other important factors to consider (*e.g.*, state of exercise).

The gas exchange curves presented in this paper are reproducible to a certain extent. This conclusion is based on repetitions of the experiment in four subjects. It would appear that under identical experimental conditions and with less than a month interval between consecutive measurements the individual variations of the amplitudes and time constants are less than the variations in a group of the same age. It is essential, however, to note that a change in physiological condition may cause a considerable change in the shape of the gas exchange curve, especially that of the hand.

A number of experimental conditions were provided to study such changes; these proved valu-

FIG. 6. VARIATIONS IN THE HAND UPTAKE CURVE OF A SUBJECT UNDER VARIOUS ENVIRONMENTAL CONDITIONS

FIG. 7. DEMONSTRATION OF RETARDATION IN THE KRYPTON ELIMINATION OF THE HAND DURING A HIGH ALTITUDE FLIGHT

The rate of elimination returned to normal after return to ground level. Note inflexion in the curve.

able in the interpretation of data. The uptake and desaturation curve of radiokrypton was influenced easiest in the hand. On subjects with cold hands usually a characteristically low gas exchange rate was obtained. This phenomenon appears to be due to a vasoconstriction of the surface blood vessels of the hand. In terms of the exponential components of the uptake curve: A_1 decreased by a factor of three or four (see Figure 6). Diathermy heating of the hand for 10 minutes with a 12 meter wavelength machine increased A_1 above normal, as shown in Figure 6, and it appeared to decrease T_2 . Heavy exercise just prior to the test (10 minutes of fast bicycle riding) increased A_1 to about twofold normal. Administration of adrenaline (0.5 cc. of 1/1000 adrenaline) had the same effect as cold skin temperature. We may thus conclude that rapidity of krypton exchange reflected the state of the vascular bed of the hand. No extensive tests were carried out for the knee

region; it was apparent, however, that the changes were considerably less in magnitude.

The rate of radioactive krypton and argon uptake was studied in a large group of young subjects in short, half-hour tests. An index was derived from these data and correlated with the incidence and severity of decompression sickness. It was found that after exposure to low atmospheric pressure, when the subjects were totally at rest in the decompression chamber, the coefficient of correlation was very high: those with low gas exchange rates got the bends, in contrast to the correlation with the incidence of decompression sickness after exercise (*e.g.*, Tables V and VI) when it was low. Since the blood flow or the carrying capacity of blood is an important factor in the rapidity of the exchange, we attempted to see whether in some way this carrying capacity could be increased. Since nitrogen and krypton are much more soluble in fats and oils than in water, it was thought that lipemia occurring some two hours after ingestion of a fatty meal might help to increase the rapidity of gas exchange, and thus relieve the danger from decompression sickness. Three subjects were given a test of three hours duration two hours after ingestion of a heavy fatty meal.⁵ The rapidity of gas exchange of the hand was not altered in these experiments.

In view of the correlation found between skin temperature of the hand and subsequent development of bends pain we attempted to detect a change in the rate of krypton exchange of the hand during decompression chamber tests. Five subjects were taken to 35,000 feet equivalent altitude for an hour to study the rapidity of krypton desaturation. All these subjects had breathed pure oxygen. Three of the subjects were free from bends pain: their desaturation curve remained normal. One subject, who on many previous occasions invariably developed bends pain in the right shoulder, showed definite slowing down of the rate of hand gas exchange in the decompression chamber, though during his 60 minute stay at high altitude he did not have any pain. The fifth subject, whose desaturation curve is plotted in Figure 7, had incapacitating bends in his left knee, right shoulder, elbow and wrist during the time his gas exchange was measured. There was again a definite slowing

of his desaturation curve in the decompression chamber. After reaching normal atmospheric pressure, the gas rate of krypton exchange curve rapidly reached normal. The changes observed fitted quite well with the general conclusions regarding the state of the circulation in decompression sickness in a different set of experiments (25), but they were not early enough or pronounced enough to be suitable for a preselection test.

It was of some interest to compare the rate of gas exchange observed on the hand of the same subject using different gases: radioactive nitrogen, argon, krypton and xenon. While we are in possession of some data more work needs to be done. The rate of gas exchange as far as components T_1 and T_2 were concerned seemed to be proportional to the solubility of each gas in water, in agreement with Jones' findings for total body uptake. T_3 , however, in the case of xenon appeared to be somewhat larger than the value predicted from solubility considerations alone.

The inert gases dissolved in the body fluids may exchange with the external atmosphere through tissues other than the lungs. Behnke and his collaborators have shown that a small fraction of total helium exchange of the body occurs through the pores of the skin (13). The mucous membranes of the intestines, especially those of the duodenum, play an important role in the secretion of a number of substances. It seemed to be of some interest to test the distribution of gases through these membranes. The gas was introduced to the duodenum by a duodenal tube. A small fraction of the gas from the duodenum rapidly got into the circulation and appeared in the extremities as well as in the exhaled air. A gamma ray counter held in one of the subject's hands recorded the rate of rise of radioactivity in the hand, and the concentration in the exhaled air was indicated by another Geiger counter tube within the spirometer. The three curves obtained on three subjects indicate that in about 15 minutes the concentration of radioactive gas in the hand reached peak value. The curves obtained show wide variation when compared with each other, however, and it is not certain whether they indicate the rapidity of uptake through the duodenal wall or whether they also depend on the nature of the aggregation of gas bubbles within the intestinal space itself. Similar experiments were performed

⁵ This consisted of one milkshake, $\frac{1}{4}$ lb. of butter and one pint of cream.

FIG. 8. UPTAKE OF RADIOKRYPTON IN HAND AFTER DUODENAL ADMINISTRATION OF ABOUT 0.5 MC. KRYPTON

with the gas administered to the stomach and to the large intestines. In these latter cases the uptake was not measurable within the first 30 minutes. The rapid exchange of gases from the intestinal tract to the circulation gives good support for recent methods of treatment for intestinal distention. If such intestinal gas consists mainly of nitrogen, then the excess gas will be absorbed by the circulation more rapidly if the patients are given pure oxygen. After a number of minutes of oxygen breathing, the dissolved nitrogen in the body becomes unsaturated and the nitrogen uptake from the intestines becomes accelerated. Other radioactive isotopes may also be used in this way to study the rate of exchange through the intestinal wall in normal and pathologic conditions.

SUMMARY

The rate of change of radioactive krypton concentration in the extremities of young male subjects has been studied. If the subjects breathed a constant concentration of radiokrypton, mixed with oxygen, the uptake and desaturation curves could be satisfactorily expressed as the sum of not more than three superimposed components, changing as the simple exponential function of time.

Exercise or heating of the hand prior to the gas exchange resulted in a generally faster ex-

change. Vasoconstriction or adrenaline caused slower exchange. A fatty meal eaten two hours before the krypton exchange had no effect on the rapidity of the test.

The gas exchange of some subjects slowed down while at 35,000 feet simulated altitude, breathing oxygen. Radioactive krypton, administered via stomach tube appeared rapidly in the circulation of the extremities and in the exhaled air of the lungs.

The techniques and results reported suggest that these radioactive gases have applications in the study of the circulation to the extremities in the living patient and in numerous problems of gas exchange in normal and pathologic states.

ACKNOWLEDGMENTS

The authors wish to thank the 60 inch cyclotron crew in Berkeley for the preparation of the radioactive gases; also Drs. W. F. Loomis and J. B. Mohnney for participating in the early phases of this work.

THE HEMODYNAMIC EFFECTS OF HYPOTENSIVE DRUGS IN MAN.

II. DIHYDROERGOCORNINE¹

By EDWARD D. FREIS,² JOSEPH R. STANTON, JULIUS LITTER,³ JAMES W. CULBERTSON, MEYER H. HALPERIN, F. CORBIN MOISTER,⁴ AND ROBERT W. WILKINS.

(From the Evans Memorial, Massachusetts Memorial Hospitals, and the Department of Medicine, Boston University School of Medicine, Boston, Mass.)

(Received for publication, April 9, 1949)

Dale in 1906 recognized the sympatholytic activity of crude extracts of ergot as well as their property of direct stimulation of smooth muscle, including that of the blood vessels (1). Despite their sympatholytic effects their direct vasoconstrictor action prevented significant lowering of arterial pressure.

Later chemical purification of the crude drug resulted in the isolation of five alkaloids: ergotamine (2), ergobasine (3), ergokryptine, ergocornine and ergocristine (4). The basic chemical structure of these compounds was clarified by Jacobs and Craig (5) who demonstrated the presence of lysergic acid in all of the alkaloids (6). By hydrogenating the reducible double bond of the lysergic acid component of four of these alkaloids, Stoll and Hofmann (7) in 1943 produced a new series of compounds, dihydroergotamine, dihydroergocristine, dihydroergocornine (DHO-180)⁵ and dihydroergokryptine (DHK-135).⁵ Pharmacological studies in animals (8) indicated that these modified compounds have enhanced sympatholytic and adrenolytic properties but little or no direct constrictor action on smooth muscle. In addition, they are hypotensive, this effect being mediated at least in part via the central nervous system (9). In man DHO and DHK in non-toxic doses have sympatholytic and hypotensive prop-

erties (10-12). Because of their possible value in the treatment of essential hypertension and peripheral vascular disease a further clarification of their hemodynamic effects in man was undertaken.

MATERIALS AND METHODS

The subjects were patients, mostly hypertensive, admitted to the wards of the Massachusetts Memorial Hospitals. The methods used in this investigation were essentially the same as those described in a previous communication (13). DHO was administered by intravenous injection in a solution of sterile water containing 0.5 mg. of active substance per cc. Unless otherwise indicated arterial pressure was measured continuously with a Hamilton manometer (13).

RESULTS

I. Sympatholytic Effects

a. Sympathetic Vasopressor Responses

Certain vasopressor responses usually abolished or diminished after surgical sympathectomy (14)

FIG. 1. OPTICAL RECORDS OF THE SYSTEMIC (FEMORAL) AND PULMONARY ARTERIAL PRESSURE DURING THE VALSALVA MANEUVER BEFORE AND AFTER THE INTRAVENOUS ADMINISTRATION OF 0.4 MG. OF DIHYDRO-ERGOCORNINE IN PATIENT F. S.

In the control period there was a marked overshoot of the systemic, but not the pulmonary arterial pressure following the release of the expiratory effort. After dihydroergocornine the overshoot of systemic pressure was completely abolished. In the respiratory tracing inspiration is down.

were completely blocked or definitely inhibited after DHO. These included:

The Valsalva Overshoot

After the intravenous administration of DHO there was complete abolition of the pressor response to the Valsalva maneuver in ten, and marked inhibition in one of 11 patients tested (Table I, Figure 1). The suppression of this vasopressor response developed gradually so that complete abolition did not occur until ten to 20 minutes after the intravenous injection of the drug.

Maintenance of Arterial Pressure During Orthostasis and the Overshoot on Tiltback

After DHO three of four patients with uncomplicated essential hypertension manifested varying degrees of orthostatic hypotension (Table II) while the fourth developed collapse two and one-half minutes after being tilted to an angle of 75°. Two other hypertensive patients who had undergone lumbodorsal splanchnicectomy (J. D. and F. T., Table II) and one normotensive patient with hyperthyroidism (V. C.) had greater postural hypotension after than before the drug. In all

cases the vasopressor overshoot which normally occurs on tilting quickly from the erect to the supine position was completely abolished by the drug.

The Cold Pressor Response

This response, which is inhibited after dibenamine (15), tetraethylammonium chloride (16), continuous caudal (17) and high spinal anesthesia (18), was partially inhibited in all nine patients tested after as compared with before the administration of DHO (Table III).

b. Digital Thermometric and Plethysmographic Responses

Of six patients examined in a room maintained at 72° F only one exhibited a significant rise in the temperature of the fingers and toes following the drug. On decreasing the room temperature to 68° F the temperature of the digits in this subject fell precipitously to below pre-drug levels. By contrast in three cases examined at a room temperature of 78° F after a control period of more than one hour the intravenous injection of DHO was followed by marked elevations of skin temperature in the digits. Thus, vasodilatation as indicated by rises in skin temperature following DHO appeared to be weak and to depend partly on the temperature of the environment.

Digit plethysmograms were recorded in four patients before and after DHO 180. The pulse volume in both fingers and toes increased after the drug in all four cases, and in three increased markedly. Re-examination of one of these patients seven hours after the drug had been administered revealed a persistence of the marked increase in pulse volume (Figure 2). Reflex vasoconstrictions to "noxious" stimuli (ice, deep breath) were abolished in one case, inhibited in one (Figure 2), and unaffected in one case. In the remaining subject reflex vasoconstrictions after ice, but not after deep breath, were abolished. The normal phasic variations in digital volume were not significantly inhibited in any one of these subjects.

II. *Blood Flow Through Various Areas*

Blood Flow Through the Forearm and Leg

The changes in blood flow in the limbs with the circulation to the hand and foot excluded (13) were determined before and after the intravenous administration of DHO in 11 hypertensive patients and three normotensive subjects. In the six patients who exhibited the greatest reduction in arterial pressure (Table IV), the mean decrease in arterial pressure was 10.9 per cent while the mean increase in blood flow was 21.3 per cent in the forearm and 10.8 per cent in the leg. Thus, peripheral resistance usually was definitely decreased in this group.

However, the average changes in the hypertensive group as a whole were not as marked. The mean blood flow in the forearm increased slightly (8.3 per cent), from 3.44 cc. per 100 cc. limb volume (range 1.68 to 6.51 cc.) to 3.66 cc. (range 1.43 to 7.80 cc. [Table V]). In the leg the mean blood flow also increased 5.4 per cent, from 3.31 per 100 cc. limb volume (range 1.94 to 5.61) to 3.44 cc. (range 1.66 to 6.20 cc.). The mean arterial pressure exhibited an average decrease of 8.7 per cent (range 1.3 to 19.4 per cent).

Although in most instances peripheral resistance decreased there were certain exceptions. In some cases, the blood flow decreased as the arterial pressure fell. Frequently, the maximum increase in blood flow in the extremities occurred before or after the arterial pressure reached its minimum, and blood flow changes in the forearm and leg often did not occur synchronously or even in the

same direction. Similar inconstant changes in blood flow were observed in three normotensive subjects (Cases 12-14, Table V).

Estimated Hepatic-Portal Blood Flow

The effect of DHO on the estimated rate of hepatic-portal blood flow was studied in four hypertensive patients (Table VI), all of whom reacted with substantial reductions in arterial pressure. In the first patient (F. A.) blood flow was reduced in each of the first three measurements after DHO, but in the fourth had returned to the control range despite a continued moderate reduction of pressure. The second patient (J. C.,

Table VI, Figure 3), five minutes after receiving DHO, had a blood flow rate still within control range in the presence of a considerable reduction in arterial pressure, but in all five subsequent observations during the ensuing 88 minutes had a proportionately greater reduction in flow than in pressure. The third patient (C. B.) resembled the first, while the fourth (C. R.) was similar to the second, except that at 24 and 36 minutes after DHO was given he developed collapse with a blood pressure of 86/50 mm. Hg. There was a spontaneous recovery and the pressure became stabilized at approximately 104/60 mm. Hg. When the effects of DHO had been observed for

more than an hour in this patient, an intramuscular injection of ephedrine sulfate (33 mg.) was given and was followed by an increase in both hepatic-portal blood flow and arterial pressure (Table VI).

All four experiments demonstrated striking re-

ductions in hepatic-portal blood flow following injection of DHO, the maximal fall from the average control level being 37, 73, 61, and 58 per cent, respectively. These were greater than the corresponding reductions in arterial pressure of 23, 20, 33,

FIG. 2

Optical records, above, of the changes in the ante-cubital venous pressure, brachial arterial pressure and finger and toe plethysmograms following the intravenous administration of 0.4 mg of dihydroergocornine in patient A. A. Following the drug a marked increase in the pulse volume of both finger and toe occurred which was still evident after seven hours. The ante-cubital venous pressure rose and exhibited an increase in arterial pulsations.

The lower tracing also illustrates the increase in pulse volume of the finger and toe plethysmograms and, in addition, shows the inhibition of the reflex responses to a deep breath and the application of ice to the forehead after 0.4 mg. of dihydroergocornine in patient E. K.

and 29 per cent, respectively. Vascular resistance appeared to be unchanged or increased in the presence of a reduced level of arterial pressure in 16 of 19 observations on the effects of this drug, suggesting that "splanchnic" arteriolar dilatation was not an important factor in the hypotensive response.

Renal Blood Flow

Of the five hypertensive patients examined two exhibited marked reductions in arterial pressure following DHO (F. A. and K. M., Table VII, Figure 4) and three had moderate reductions. In patient F. A. the arterial pressure fell suddenly from 300/150 to 167/90 over a period of three and one-half minutes after the drug. This sudden hypotensive response was accompanied by a marked

fall in renal plasma flow from 300 to 90 cc. per minute. However, the renal plasma flow returned to control values during the next ten minutes despite only partial return of the arterial pressure. The changes in renal plasma flow followed a similar pattern in patient K. M., while in the remaining three patients, in whom arterial pressure changes were not marked, the renal plasma flow decreased slightly, remaining somewhat depressed in two and increasing in the other after 25 minutes to approximately control levels. Thus, in all five cases renal plasma flow decreased initially; it remained slightly depressed in two and returned to approximately control values in three.

It is of interest that in subject F. A. both renal and hepatic-portal blood flow rates were estimated

FIG. 3. CHART OF THE CHANGES IN ESTIMATED HEPATIC-PORTAL BLOOD FLOW, ARTERIAL PRESSURE AND HEART RATE (HAMILTON) BEFORE AND AFTER THE INTRAVENOUS ADMINISTRATION OF 0.35 MG. OF DHO IN PATIENT J. C.

Five minutes after DHO during a sudden reduction in arterial pressure the hepatic-portal flow was maintained indicating a decrease in peripheral resistance. Following this initial period, however, the hepatic blood flow fell, gradually returning toward control values 85 minutes after the drug was administered. Calculated "crude peripheral resistance" remained increased following the initial period.

Summary of effects of dihydroergocalcium on the arterial pressure and the blood flow in the arm and leg

† Ephedrine sulfate (33 mg.) was injected intramuscularly at 65½ minutes after the injection of dihydroergocornine.

during a single experiment (Tables VI and VII, Figure 4). The marked fall in average renal blood flow for the first ten minute period of urine collection after injection of DHO, which included the time of sudden fall in arterial pressure, has been noted above. Hepatic-portal blood flow apparently fell similarly, but it was not measured at the time of greatest hypotensive response. However, in the second period, when renal blood flow was completely restored, hepatic-portal blood flow was greatly reduced; though it subsequently increased gradually, to regain the control level 32 minutes after administration of the drug.

III. Renal Function

Glomerular filtration rate usually paralleled the changes in renal plasma flow (Table VII, Figure 4). As a consequence there was little change in the filtration fraction. The most consistent change was in the urine flow which uniformly decreased and remained well below control values, even when

the glomerular filtration rate and renal plasma flow had returned to pre-drug levels.

IV. Cardiac Output, Mean Arterial Pressure and Total Peripheral Resistance

Changes in the cardiac output (catheterization method) in systemic arterial pressure (Hamilton method) and pulmonary arterial pressure were determined in two hypertensive and two normotensive subjects before and after the administration of DHO (Table VIII). In the two hypertensive subjects following the injection of 0.30 and 0.40 mg. of DHO intravenously the mean arterial pressure fell 21 and 10 per cent, while the cardiac output increased 6 and 14 per cent, respectively. As a result the total peripheral resistance fell 25 and 20 per cent, respectively.

Whereas the hypertensive patients were studied only in the supine position, the two normotensive subjects were tested in both the supine and semi-erect positions (tilted upright to an angle of

FIG. 4. CHART OF EFFECTIVE RENAL BLOOD FLOW, GLOMERULAR FILTRATION RATE, FILTRATION FRACTION, URINE FLOW, ARTERIAL PRESSURE AND PULSE RATE BEFORE AND AFTER THE INTRAVENOUS INJECTION OF 0.4 MG. OF DHO IN PATIENT F. A.

In the initial period there was a decrease in renal blood flow, glomerular filtration rate and urine flow associated with a reduction in arterial pressure and pulse rate. However, ten minutes after DHO, renal blood flow and glomerular filtration rate returned to control values despite continued significant reduction in urine flow, arterial pressure and pulse rate.

20 to 30°). In the two normotensive subjects, in the supine position, the changes following the drug were qualitatively similar to those observed in the hypertensive subjects. After DHO, the mean arterial pressure decreased 12 and 7 per cent, respectively, the cardiac output increased 11 and 3 per cent, while the total peripheral resistance fell 21 and 10 per cent.

Pulmonary arterial pressure was not significantly changed after DHO in any of the subjects. In the semi-erect position one of the normotensive subjects tolerated the 30° tilt for the five minute

test period without discomfort. Whereas before the drug the mean arterial pressure rose during the tilt, after the drug it fell (postural hypotension). When the table was tilted to 30° the cardiac output fell both before and after the drug, but more so after, and in both instances the total peripheral resistance rose. Thus, in this subject the postural hypotension appeared to be associated with a diminished cardiac output. The second normotensive subject (E. R., Table VIII) was not able to tolerate the 30° tilted position after the drug and developed early signs of collapse in-

cluding weakness and sweating. He was tilted back to an angle of 20°, a position he could tolerate, and the determinations were then carried out. The mean arterial pressure fell slightly from 91 mm. supine to 88 mm. Hg during the 20° tilt, but the cardiac output increased markedly from 6.55 liters at 0° to 9.2 liters per minute at 20°. Since the patient was recovering from incipient collapse during this period the increase in cardiac output may have been associated with compensatory reactions occurring with the recovery.

V. Other Effects

Heart Rate

A decrease in heart rate following DHO was noted in the present cases as well as in subjects studied previously (10, 11, 19) (Table VIII, Figure 4). In addition, the reduction of arterial pressure in the erect position after DHO, unlike that after lumbodorsal splanchnicectomy or the administration of tetraethylammonium, was not accompanied by tachycardia (Table II).

The bradycardia was only partially abolished by the administration of doses of atropine sulfate which ordinarily produce significant tachycardia in man (0.75 to 1.0 mg. intravenously). In four patients in whom atropine was injected following DHO the acceleration of heart rate varied from 6 to 19 beats per minute. In no instance was the administration of atropine followed by definite tachycardia.

The Response to Venous Congestion of the Extremities

Investigations in this laboratory (20) have disclosed that drugs which cause postural hypotension may cause similar hypotension and collapse in patients who are supine when the venous return from the extremities is compromised by inflating at slightly below diastolic pressure pneumatic cuffs placed proximally about the thighs and one upper arm.

Prior to the drug three hypertensive subjects tolerated such congestion of the extremities for five minutes with no significant alterations in arterial pressure. However, after 0.5 mg. of DHO intravenously two of the three subjects developed hypotension, bradycardia and collapse between four and five minutes after the application of sim-

ilar congesting pressures to the same regions. The significance of these results with respect to the mechanism of the collapse and the effects of other drugs will be reported in another communication (20).

Effect of DHO and DHK on the Response to the Intravenous Administration of Epinephrine

The dihydrogenated alkaloids of ergot are reported to inhibit the pressor response to epinephrine in the anaesthetized experimental animal (8). Similarly in unanaesthetized animals (8) and man (11), DHK may block the hyperglycemic response to epinephrine.

The adrenolytic properties of DHO and DHK on cardiovascular functions were investigated by the use of gradually increasing intravenous doses of epinephrine instantaneously injected. As noted previously in this laboratory (21), the characteristic response to minimal (0.5 to 1 µg.) doses of epinephrine thus administered is mainly depressor and is accompanied by cardiac acceleration and a slight increase in the antecubital venous pressure. After slightly larger doses of epinephrine the depressor response, while still present, is followed by a later pressor phase which increases in magnitude and duration with the dose of epinephrine.

Both DHO and DHK inhibited the depressor phase when single doses of 0.5 to 1.0 µg. of epinephrine were administered intravenously (Table IX). The inhibition was least evident in the response of the arterial pressure, more apparent in the heart rate, and most evident in the response of the venous pressure. However, with increasing doses of epinephrine (2 µg.) inhibition of the depressor phase was not consistent. Further, in the pressor phase of the epinephrine response the rise in arterial pressure was not significantly altered by either DHO or DHK, although the tachycardia and rise in venous pressure were slightly inhibited. Thus, in contrast with the results obtained in experimental animals (8), the dihydrogenated alkaloids of ergot in the doses used appeared to have only slight adrenolytic activity with respect to these cardiovascular functions in man. It is of interest, however, that in a patient with pheochromocytoma both a continued hypertension as well as a marked pressor reaction

† Hamilton manometer recordings from the antecubital veins.

to the histamine test were promptly relieved by intravenously injected DHK (22).

Since it has been suggested that the pressor and cardio-accelerator responses to emotional stimuli may be due at least in part to epinephrine discharge (23) it was considered of interest to de-

termine the effect of the emotional stimulus of a problem in mental arithmetic on the arterial pressure before and after DHO. Of three patients tested the pressor response was reduced in two after as compared with before DHO, while the accelerator reaction was reduced in all. These re-

sults must be interpreted with caution, however, since such stimuli tend to lose emotional impact on repetition.

"Vascular Distensibility" in the Extremities

At intervals during the studies of limb blood flow the "vascular distensibility" (increase in volume during graded venous congestion) in the forearm and leg was determined in 14 subjects according to the method of Litter and Wilkins (24). In almost all cases there was a significant decrease in the vascular distensibility, which occurred more consistently than any of the changes in limb blood flow, but did not correlate with either the fluctuations in arterial pressure or the blood flow. The significance of these findings will be discussed elsewhere (24).

Venous pressure in the antecubital vein, recorded in four subjects with a Hamilton manometer, rose 1 to 4 mm. of mercury, after DHO. The marked increase in peripheral venous pressure during the Valsalva maneuver was also considerably greater after as compared with before DHO. In addition, arterial pulsations became more prominent in the antecubital venous recordings after the drug (Figure 2).

DISCUSSION

This investigation supplied additional evidence confirming the conclusions of Bluntschli and Goetz (10) that DHO has sympatholytic effects in man. It disclosed that DHO not only inhibits vasoconstriction in the extremities, but also depresses vasopressor responses mediated over sympathetic pathways.

The bradycardia which frequently follows the injection of the dihydrogenated ergot alkaloids also appeared to be due in part to inhibition of the sympathetic cardio-accelerator mechanism, since after DHO doses of atropine sufficient to inhibit vagal influence on cardiac rate failed to produce significant tachycardia. In contrast to their apparent sympatholytic effects, the dihydrogenated alkaloids in the doses used had only slight adrenolytic properties so far as the immediate cardiovascular reactions to injected epinephrine were concerned. Such evidence suggests that the circulatory changes observed in the present studies in man may have been due to the central action rather

than the peripheral sympathetic-blocking effects of these drugs (8, 9).

The fall in arterial pressure following DHO, except in the semi-erect position, was associated with maintenance of cardiac output, and, hence, with a decrease in total peripheral resistance. The maintenance or slight increase in cardiac output may have been influenced by any one or a combination of the following factors: 1) the maintenance of right cardiac filling pressure as evidenced by the rise in peripheral venous pressure and unchanged pulmonary arterial pressure, 2) the cardiac slowing which permitted more effective diastolic filling, and 3) the diminished peripheral resistance. A similar hemodynamic response was observed after veratrum viride (13), the action of which also involves the vascular centers in the nervous system. Such a response is in marked contrast to that caused by certain peripherally acting vasodilators such as sodium nitrite after which cardiac output falls in association with compensatory tachycardia and a decrease in venous and pulmonary arterial pressure (25).

Although *total* peripheral resistance decreased uniformly after DHO the pattern of blood flow in discrete peripheral areas exhibited marked fluctuations. In the renal area the blood flow decreased early, but later increased to or toward control values. Blood flow in the muscles usually increased and in the splanchnic area usually decreased, but these changes were inconstant. Thus, peripheral resistance in different regions might increase, decrease, or vary from one direction to the other during a reduction in blood pressure. In this regard it is of interest that Hafkenschiel and his co-workers (26) found that cerebral vascular resistance was reduced after DHO in hypertensive, but not in normotensive subjects.

This lack of uniform response may indicate that the hypotensive effects of the drug had called forth counteracting mechanisms; or that the drug itself had multiple effects, including opposing actions on the blood vessels. The constrictor action on arteriolar muscle that is exhibited by the naturally occurring ergot alkaloids is said to be minimal with the dihydrogenated derivatives in animals (8), and in the digits of man (10). However, it is possible that in the muscular and hepatic-portal areas of man the direct vasoconstrictor

effect may become active and at times may be occasionally dominant.

Either hypothesis, 1) activation of compensatory vasoconstrictor mechanisms, or 2) multiple opposing actions of the drug, could explain not only the variable changes in blood flow in the splanchnic bed and muscles, but also the apparent failure of DHO to bring about a hypotensive response in certain patients despite evidence of inhibition of sympathetic reflex vasoconstriction (11). The possibility that the hypotensive effect of the drug may be due to some property other than a sympatholytic action also cannot be excluded.

The only peripheral areas studied which manifested a consistent pattern of vasodilatation were the hands and feet when the subjects were examined in a warm room. A decrease in peripheral resistance was manifested by a rise in skin temperature, an increase in pulse volume, and by the presence of arterial pulsations in the venous pressure recordings taken from the antecubital vein. The rise in antecubital venous pressure after DHO in all probability was secondary to the increased arterial inflow, resulting from the local arteriolar vasodilatation without a correspondingly increased venous outflow. The increased pulsation in the veins could have been due partly to transmission from neighboring arteries across intervening tissues. However, this seems unlikely since 1) the pulse in the larger arteries, such as the brachial and radial, became less, rather than more bounding after the drug, 2) the increased pulsation also was observed in superficial veins remote from larger arteries, and 3) since there was obvious evidence of peripheral arteriolar vasodilatation, particularly in the digits, transmission of the pulse waves through the dilated vascular beds to the veins seems a more likely explanation for their presence in the venous tracings.

There were many points of similarity between DHO and tetraethylammonium. Both drugs inhibited sympathetic vasoconstrictor reflexes (27), raised skin temperature in the digits (28), produced an initial decrease in renal clearances followed by a return to control values (29), and as a rule increased limb blood flows (28, 30). The chief points of difference were that after tetraethylammonium the cardiac output either decreased (31) or remained unchanged (28), the

heart rate increased (32) and the pulmonary arterial pressure decreased (31). The reason for these differences is not clear unless they were related to the different sites of action of the two drugs (8, 33).

It was of interest also to compare the effects of DHO with those of veratrum viride, since the hypotensive action of both drugs is believed to be mediated through the central nervous system (9, 34). The two drugs were similar, in that both could decrease arterial pressure and heart rate without depressing cardiac output, they both produced oliguria, and brought about a decrease in renal blood flow during the early, falling phase of the hypotensive response. They were dissimilar in that following suitable doses of veratrum viride significant hypotension occurred almost without exception, the changes in peripheral resistance were uniform in all the vascular areas studied, and the homeostatic vasoconstrictor reflexes remained intact. Atropine abolished the bradycardia induced by veratrum, but not that which followed DHO, while "vascular distensibility," in the extremities, which increased following veratrum, usually decreased after DHO.

Clinically these studies suggest that sympatholytic agents have certain fundamental limitations in the treatment of essential hypertension. First, as has been observed with other agents that inhibit sympathetic vasoconstrictor reflexes (32, 35, 36), not all patients had a significant reduction in arterial pressure following the administration of DHO. Thus, the therapeutic use of this agent, as of other sympatholytic drugs, would seem to be limited to selected patients. Second, its apparent blockade or inhibition of reflex vasoconstrictor mechanism so interfered with homeostasis that at times vascular collapse seemed imminent or actually occurred. Finally, after it had been given, the changes in peripheral resistance in different vascular beds were so varied and unpredictable as to suggest that certain factors opposing a uniform vasodilatation were active.

SUMMARY AND CONCLUSIONS

Dihydroergocornine (DHO) administered intravenously in man produced the following hemodynamic effects:

1. Vasopressor responses to blood-pressure-lowering procedures (Valsalva maneuver, upright tilting), and to the immersion of a hand in iced water (cold test) were inhibited or abolished. Skin temperature in the digits exhibited significant increases in a warm, but not in a cool environment. Digital pulse volumes increased, and reflex vasoconstrictor responses to "noxious" stimuli usually decreased.

2. Blood flow through the forearm and leg frequently increased as the arterial pressure fell, but it sometimes decreased or remained unchanged.

3. Blood flow through the hepatic-portal circuit also varied in different patients, occasionally remaining at control levels early in the hypotensive response, but usually becoming reduced proportionately more than the arterial pressure. The variability of the responses in blood flow in the limbs and in the hepatic-portal region suggests that the drug may have multiple and opposing effects, or that after it has been given, certain counteracting vasoconstrictor mechanisms may become activated.

4. Renal blood flow decreased initially, but in three of five patients it later returned to control levels. Glomerular filtration rate paralleled renal blood flow. Hence, there was little change in the filtration fraction. Oliguria occurred and persisted even when renal plasma flow and glomerular filtration rate returned to control values. Therefore, the oliguria appeared to be secondary to increased tubular reabsorption of water.

5. The fall in arterial pressure in the supine position was accompanied by no change or a slight increase in cardiac output. Total peripheral resistance, therefore, was reduced. The bradycardia accompanying the hypotensive response was not abolished by atropine.

6. Venous congestion by cuffs high on the extremities could precipitate collapse in supine patients who had received DHO.

7. "Vascular distensibility" in the limbs usually decreased, while venous pressure in the arm rose. Arterial pulsations became more prominent in the venous pressure recordings taken from the ante-cubital vein.

8. The alkaloids, dihydroergocornine and dihydroergokryptine, opposed only slightly the effects of epinephrine on the arterial pressure and heart rate of man.

THE EFFECT OF A CATION EXCHANGE RESIN ON ELECTROLYTE BALANCE AND ITS USE IN EDEMATOUS STATES

By LESLIE IRWIN, EUGENE Y. BERGER, BENJAMIN ROSENBERG, AND
ROSLYN JACKENTHAL

(From the Third New York University Research and Medical Services, Goldwater Memorial Hospital, Welfare Island, New York, N. Y.)

(Received for publication April 25, 1949)

In ancient Greece, "terra sigillata" or "sealed earth" was reputed to be a successful counter agent for poisons (1). Its fame grew through the centuries commensurately with the refined custom of poisoning one's dinner partner.

Early trials of the effectiveness of "terra sigillata" are reported in two 16th century documents (2). The first, dated 1580, records that of eight dogs who were fed various poisons, including mercury sublimate, the four that received "terra sigillata" survived, while the others died. A 1581 account details another successful experiment in which the "earth" was administered to a condemned criminal immediately following "a dram and a half of Mercurie Sublimate."

"Terra sigillata" was found, in 1914, to consist of oxides of calcium and aluminum with a large proportion of silicates (2). Thompson, the analyst, attributed "its virtues . . . chiefly due to the mystery surrounding its origin and the superstitions connected with its source." In the light of more recent knowledge, however, the action of "terra sigillata" may well be explained on the physico-chemical grounds of an ion exchange.

Ion exchangers are insoluble substances which remove ions from solution by releasing one ion in exchange for another (3-6). Way, in 1850, first observed the phenomenon of ion exchange in soil (7). Subsequently a number of naturally occurring substances were found to have cation exchange properties but were of limited use because of their low exchange capacity and chemical instability (8, 9). Advances over the naturally occurring substances were the development of "zeolites" from sodium aluminate and sodium silicate (10-13), and of synthetic organic exchangers from sulfonated coals (14). In 1934, Adams and Holmes prepared synthetic phenol-formaldehyde resins with cation exchange properties and introduced resins prepared from aromatic amines and formal-

dehyde which were capable of exchanging anions (15).

In 1945 anion exchange resins, which remove such ions as chloride, sulfate, and phosphate from solution, were utilized in the therapy of peptic ulcer (16-18). The next year Dock suggested that cation exchange resins, which remove such ions as sodium, potassium, calcium, and magnesium from solution, be used to take up sodium from ingested food. He showed that the particular resin he used was non-toxic in dogs and rats when fed in massive doses over a two-week period (19).

The present study concerns observations of electrolyte interchange between a cation exchange resin and medium, *in vitro* and *in vivo*. The resin was also evaluated in the therapy of congestive heart failure and cirrhosis of the liver by comparing measures needed to control accumulation of fluid with and without resin. The resin used was Liquonex CRW¹ passed through a 120 mesh screen. The insoluble cation exchange resin is a sulfonated polystyrene capable of neutralizing from 3.9 to 4.5 mEq. of base per gram of resin.

PROCEDURES

In vitro: Solutions of known composition were mixed with the resin and the surrounding fluid analyzed in order to determine the proportions of various ions removed under a variety of circumstances.

In vivo: A constant diet was fed to a subject and the effect of oral administration of resin on his electrolyte balance was observed. The subject, a 59 year old male, had neither history nor sign of cardiac or renal dysfunction although he had a mild systolic hypertension and a right hemiparesis. He was cooperative enough to consume the following three meals daily for 80 days. Breakfast consisted of tomato juice, two eggs, a slice of bread with a pat of butter and a glass of milk. Dinner and supper consisted of two ounces of ham, a potato, one

¹The authors are indebted to Dr. Sidney Sussman (Liquid Conditioning Corp., Linden, N. J.) for the preparation and supply of this resin. Liquonex CRW is essentially Dowex 50.

slice of bread with a pat of butter, a glass of milk and grapefruit. On analysis the diet was found to contain 112 mEq. of sodium, 87 mEq. of potassium, 47 mEq. of calcium, 118 mEq. of chloride, 44 mM of inorganic phosphorus, and 11.9 grams of nitrogen (75 grams of protein). Water was allowed ad libitum.

After a period of 20 days on the diet an amount of resin was administered each day equivalent to 100 mEq. of base. One-third of the daily dose of resin was ingested in plain gelatin capsules during each meal. After nine days the dose was increased to 150 mEq. Twelve days later the dose was increased to 200 mEq. and then in eight days to 250 mEq. After six days on 250 mEq. the resin was discontinued and the patient was observed for an additional 25 days.

The subject was weighed daily. Twenty-four hour urines were collected under oil using toluene as a preservative. The urinary specific gravity, volume, creatinine, pH and titratable acid, total nitrogen, ammonia, sodium, potassium, calcium, inorganic phosphorus, sulfate and chloride were determined. The feces were collected in three-day periods, dried under an infra-red lamp, weighed and ground to a fine powder in a mortar and analyzed for total nitrogen (less ammonia nitrogen), inorganic phosphorus and chloride. Aliquots of the dried feces were treated with concentrated sulfuric acid, ashed overnight at 800° C and analyzed for sodium, potassium and calcium. At 10-day intervals determinations were made of the plasma sodium, potassium, calcium, phosphorus, carbon dioxide combining power, chlorides, pH, urea nitrogen and alkaline phosphatase.

Urinary specific gravity was determined with a urinometer. Urinary pH was determined under oil and the urine was then titrated to pH 7.4 with 0.02 N sodium hydroxide. Sodium and potassium were determined with an internal standard flame photometer (20). Calcium was measured by dissolving the precipitated oxalate in 2 N sulfuric acid and adding an excess of hexanitratammonium cerate. The cerate was back titrated with ferrous ammonium sulfate using ortho-phenanthroline ferrous sulfate as an indicator. Chloride was determined according to Wilson and Ball (21); phosphorus accord-

FIG. 1

ing to Fiske and Subbarow (22); ammonia and urea according to Summerson's modification of the Van Slyke and Cullen procedure (23); creatinine by a modification of the Folin method (24). Sulfate was determined by a turbidimetric method using barium chloride (25). Total nitrogen was determined by the micro-Kjeldahl technique. Phosphatase was determined by the King and Armstrong method (26).

OBSERVATIONS

In Vitro

Liquonex CRW like other hydrogen exchange resins removes sodium from solution by forming an insoluble combination of sodium and resin, releasing a free hydrogen ion for each sodium ion fixed to the resin.

As the amount of sodium added per gram of resin was increased, more sodium was removed per gram until the resin was saturated (Figure 1). The volume of water in which the sodium was dissolved had little effect on sodium removal by the

TABLE I

* Resin capacity 3.9 mEq. of base per gram

resin. Studies of combinations of sodium and resin which would approximate the ratio encountered in the intestine revealed the resin to be incompletely saturated with sodium. Therefore, if the amount of salt is increased in a diet containing a constant amount of resin, a goodly proportion of the increment will be fixed to the resin.

Ions of higher valence or higher molecular weight tend to occupy the resin in preference to ions of lower valence or lower molecular weight (Table I) (27). The resin had a greater affinity for potassium and calcium than for sodium regardless of the medium in which these ions were dissolved. The capacity to remove cation was enhanced in alkaline solution. Sodium, potassium, and calcium in solution in the proportions present in the diet did not affect the preferential removal of potassium and calcium over sodium.

Sodium and potassium chloride were added to milk to approximate the proportions of sodium, potassium, and calcium in the diet. The pH of this solution was 6.8. Ultrafiltration by a Sims ultrafilter revealed 56 per cent of the calcium to be bound to protein. The same solution was also studied after the pH had been adjusted to 5.0 with dilute acid and to 7.5 with dilute alkali. None of these manipulations affected the affinity of the resin for potassium and calcium over sodium. Calcium bound to the protein left the protein to occupy space on the resin.

Using a solution in which the ratio of ions was such as is found in the fluid of the ileum (140 mEq. of sodium, 5 mEq. of potassium, and 5 mEq. of calcium), 64 per cent of added sodium was removed. In this instance, 1.32 mEq. of sodium were removed per gram of resin whereas the maximum amount of sodium removed per gram of resin in the other combinations was 0.8 mEq. per gram. This is a result of the higher ratio of sodium to calcium and potassium.

The action of a cation exchange substance is not limited to inorganic cations alone but basic organic materials adhere as well. When a solution containing 123 mg. of nitrogen as glycine, a relatively neutral amino acid, was added to a gram of resin, 50 per cent of the glycine was fixed to the resin. Likewise, when 157 mg. of nitrogen as a mixture of amino acids in solution (Amigen) were added to a gram of resin, 31 per cent of the amino acids was fixed to the resin. It must be

recognized that this type of experiment does not indicate the firmness of the bond between the amino acid and the resin.

In Vivo

These observations of the action of the resin suggested the alterations in electrolyte balance that might be anticipated *in vivo*. The actual alterations were measured following resin administration to a human subject.

The subject remained well and symptomless throughout the period of resin administration except for the last day when he was nauseated. He fully recovered in 24 hours. During the 80 days of resin administration the subject lost 3.6 kg. of weight which he regained by the ninth day after resin was discontinued. The mean urinary volume was greater during resin administration (2110 ml.) than during the control period (1640 ml.). The larger volume of urine excreted is for the most part accounted for by the extra water necessary to help swallow the capsules.

Urinary excretion of sodium averaged 109 mEq. per day during the control period. As the daily dose of resin was increased from 106 to 250 mEq., urinary sodium excretion fell to 10 mEq. per day (Figure 2). There were certain vagaries in urinary sodium excretion that corresponded with

* Combining power

weight changes, the explanation of which is not clear. For ten days after the discontinuance of resin, it remained low (10 mEq. per day) and was then followed by a profuse diuresis of 325 mEq. per day before returning approximately to the level of the dietary intake. Plasma sodium did not vary appreciably during the study (Table II).

The patient experienced constipation towards the end of the resin period. This accounts for the low fecal excretion of sodium and potassium at this time (Figures 3 and 5). The feces for 13

was receiving 200 to 250 mEq. of resin per day, the fecal sodium representative of this period was about 80 per cent of the dietary sodium (Figure 3).

Urinary potassium excretion did not show the fluctuations that occurred in the urinary sodium excretion (Figure 4). From a mean control value of 78.5 mEq. per day it fell over a period of 30 days to a level of 7 mEq. per day as the dosage of resin increased. After the discontinuance of the resin the potassium excretion also remained at a low level for 10 days before it rose to equal the dietary intake. Plasma potassium remained relatively stable except for one value of 2.6 mEq. per liter toward the end of resin administration. Mean daily fecal potassium excretion increased from 5.8 mEq. during the control to 58.6 mEq. during resin feeding (calculated similarly to the sodium). Fecal potassium during resin administration was thus 68 per cent of the dietary potassium.

Mean daily urinary calcium excretion was 13 mEq. during the control period, 8.8 mEq. during resin administration and 11.2 mEq. in the post-resin period. The mean daily fecal calcium excretion was 40 mEq. during the control period and

FIG. 3

days after the resin was discontinued contained normal amounts of nitrogen while the weight indicated that resin was still present. Consequently, feces excreted in these 13 days may be considered as part of the resin period. On this basis, the mean fecal excretion of sodium increased from 1.4 mEq. per day during the control to 51.0 mEq. per day during the resin period.² At the time the patient

²Liquonex CRW itself contains a small amount of sodium and the fecal excretion of sodium has been accordingly corrected.

FIG. 4

FIG. 5

35.1 mEq. during resin administration (Figure 6). Statistically the mean daily excretion of urinary or fecal calcium did not differ among these periods. There were no appreciable changes in plasma calcium or alkaline phosphatase.

FIG. 6

During the control and resin periods dietary sodium, potassium and calcium compared well with the urinary plus fecal output of these ions. Balance studies thus failed to indicate loss of sodium, potassium or calcium from the body.

The mean daily urinary excretion of chloride, phosphate, and sulfate were not appreciably different in the control, resin and post-resin periods. They were respectively 124, 110 and 121 mEq. for chloride; 27.5, 29.7 and 22 mM for phosphate; and 32.3, 37.0, and 38.6 mEq. for sulfate. There were no appreciable changes in the fecal excretion of chloride or phosphorus. Plasma phosphorus was not altered.

The reduced absorption of sodium and potassium from the gut in the presence of a relatively constant absorption of chloride, phosphate, and

sulfate illustrates the mechanism of the acidosis induced by the resin. As resin administration progressed, plasma carbon dioxide combining power fell from 27 to 19 mM per liter and the chloride rose from 102 to 112 mEq. per liter with no significant change in pH of blood (Table II). This exemplifies the compensated metabolic acidosis described by Gamble (28).

The kidney balanced the excess chloride, phosphate and sulfate relative to sodium and potassium by formation of ammonia (Figure 7). Ammonia production increased from a mean value of 25 mEq. per day during the control period to 211 mEq. per day on the 34th day of resin administration. The mean urinary pH during the control periods was 6.3 and during resin feeding was 6.0. The mean daily titratable acidity increased from 17.2 mEq. during the control period to 25.6 mEq. during the resin period. It may be seen that the shift in pH did not contribute greatly to balance the anion excess. It is of interest that additional calcium was not excreted in the urine to help balance this anion excess.

URINARY ELECTROLYTE PATTERN DURING CONTROL AND RESIN PERIOD

FIG. 7

The mean daily excretion of urinary nitrogen for control and resin periods was 10.2 and 10.5 grams respectively. In the first 10 days following discontinuance of the resin, urinary excretion of nitrogen fell to a daily mean of 8.8 grams following which the mean was 10.5 grams. The mean daily fecal nitrogen was 0.68, 0.68, and 0.61 grams for the control, resin and post-resin periods respectively. Except for the 10 days immediately after discontinuance of the resin, where there was a retention of nitrogen, total nitrogen intake of 11.9 grams compared well with total output. There was no consistent change in blood urea nitrogen.

Clinical Application

Two pertinent effects were noted in the administration of resin to this subject. Sodium was immobilized in the gut and a compensated metabolic acidosis was produced. These two situations would be acceptable in the therapy of edematous states. The resin was therefore tested for its usefulness in the therapy of two cases of congested heart failure and one case of cirrhosis of the liver with ascites and edema.

The patient A. C. was a 62 year old male with luetic heart disease and aortic insufficiency. He was observed for six weeks on a regular diet containing approximately 6 grams of salt. Moderate compensation was maintained with three 2 ml. injections of mercurhydrin each week plus 0.1 gram of digitalis daily. At the end of this six-week period mercurials were discontinued but the diet and digitalis were maintained. The patient was begun on gradually increasing doses of resin starting at 100 mEq. daily. After a slight weight gain during the first four days, his weight stabilized for the succeeding four days, whereupon he began to lose weight. As the dosage of resin was increased to 270 mEq. daily over a 16-day period, there was a 2.5 kg. weight loss. The resin was discontinued and he promptly gained 4.6 kg. in 10 days. The resin was again instituted and the patient lost 2.7 kg. in five days.

The patient C. G. was a 55 year old white female with rheumatic heart disease. During a control period of 37 days on an acid ash diet containing 3 grams of sodium chloride, she required 0.1 gram and 0.2 gram of digitalis every other day and 2 ml. mercupurin about every five days. Her greatest weight during this period was 46.9 kg., her lowest was 41.4 kg. With institution of resin in daily dosage of 230 mEq., diet was changed to one containing 6 grams of salt daily, mercupurin was discontinued, digitalis dosage was maintained. The patient's weight fell from 46.9 kg. to 42.2 kg. in 12 days. At this time the patient vomited. Digitalis toxicity was considered to be the cause and both digitalis and resin were discontinued. Serum carbon dioxide combining power was normal. Digitalis was resumed after five days in

daily dosage of 0.1 gram and the resin was resumed after 10 days. During the 10 days without the resin her weight increased from 42.2 kg. to 47.3 kg. With daily dosage of 150 to 200 mEq. of resin, she maintained a weight of 45.5 kg. over a 40-day period without requiring mercupurin. Plasma carbon dioxide combining power and plasma potassium were not altered in this period. When the resin was discontinued she gained 2 kg. in four days and experienced a return of paroxysmal nocturnal dyspnea.

The patient J. O. was a 52 year old white male with symptoms of decompensated cirrhosis of the liver with abdominal ascites and peripheral edema. During a seven-week observation period in the hospital, he accumulated fluid at a rate which required mercupurin every 10 days. His greatest weight was 59.4 kg., and his lowest, 56.0 kg. following mercupurin. With the institution of resin in dosage of 100 mEq. per day, his weight fell from 57.4 to 53.5 kg. in 12 days. The patient maintained his appetite fairly well during these 12 days but with the loss of edema fluid, cachexia became apparent. At this time plasma carbon dioxide content had fallen from 24.5 to 13.8 mM per liter, plasma chloride rose from 101 to 110 mEq. per liter and potassium rose from 2.9 to 5.9 mEq. per liter. Oral administration of the resin, however, was continued for another 10 days. There was a further weight loss to 49.5 kg. at which point ascites could not be detected clinically. The patient became anorexic. Plasma carbon dioxide content fell to 8.5 mM per liter, chloride rose to 114 mEq. per liter, potassium was 2.3 mEq. per liter. The resin was discontinued and alkalizing solutions containing potassium (15 mEq. per liter) were administered intravenously. Although the patient was cachectic and weak, he did not appear critically ill, when he suddenly developed an aberrant ventricular rhythm and expired.

DISCUSSION

Cation exchange resins taken orally reduce the absorption of sodium from the intestine. When an amount of resin sufficient to neutralize 150 mEq. of base was fed daily with a diet containing 100 mEq. of sodium (6 grams of salt), urinary excretion of sodium was reduced to 50 mEq. per day. Feeding 250 mEq. of resin with the same diet reduced daily urinary excretion of sodium to 8 mEq.

Salt restriction is, of course, important in the management of congestive heart failure. Its application, however, requires the patient to submit to the rigors of a selective diet. With the use of a cation exchange resin, the patient may satisfy his appetite within reasonable limits without absorbing excessive amounts of sodium. During periods of resin administration in two edematous patients

with heart failure there was a diuresis of existing depots of fluid and edema failed to reaccumulate.

In the case of cirrhosis of the liver, use of the resin orally was also successful in preventing the absorption of sodium from the gut. Since the most important part of the treatment of cirrhosis is a dietary regime high in protein, and since devising a high protein, low salt diet is difficult, the use of resin might be an important addition to therapy of this condition.

Unfortunately, sodium is not the only ion, but is, in fact, the ion least likely to occupy the resin when in competition with potassium or calcium. From the balance study it did not appear that the subject lost more potassium than he consumed. There was, however, very low urinary excretion of potassium for 10 days after the resin was discontinued. In view of the gain in weight of 3.6 kg. and the daily retention of 1.4 grams of nitrogen, during a period of low excretion of potassium and sodium it would appear that tissue and water were being replaced.

A calcium deficit would normally be anticipated from the *in vitro* observations, but did not occur in the balance study. The availability of calcium for absorption is closely related to the presence of insoluble complex acid radicals (*i.e.*, oxalates, phytates) (29). The resin produces, in effect, a markedly acid diet which would increase the availability of the insoluble calcium for absorption (29). This may or may not be the explanation, but the fact remains that the subject did not develop a detectable calcium deficiency.

The secretion of sodium, potassium and calcium into the lumen of the gut and their subsequent reabsorption creates an active interchange of electrolytes across the gut wall. Of the ions to which the resin is exposed in its passage down the gut, the amount of sodium is by far in excess of potassium or calcium. Thus, a larger portion of the resin was occupied by sodium *in vivo* than was anticipated by the studies *in vitro*.

Consideration must also be given to cations other than sodium, potassium, and calcium; in particular, magnesium, iron, manganese, copper and cobalt. Prolonged feeding of exchange substances may well lead to a deficiency of one or another of these cations. Since basic organic ma-

terials are also fixed to resin, these substances, too, must be considered. In the balance study, fecal nitrogen did not increase during resin feeding. It may be inferred from this fact that there were no excessive losses of amino acids in the stool. The losses of other basic organic substances (riboflavin, thiamin) were not measured. The magnitude of the problem of creating a deficiency as a result of the possible losses of these basic organic substances remains to be evaluated. The deficiency would depend greatly on the strength of the bond between the organic base and the particular exchanger.³

In exchange for cations, Liquonex CRW releases free hydrogen ion into the gut. Resin feeding is consequently equivalent not only to restricting salt intake but also to concomitantly administering 5-10 grams of ammonium chloride daily. With the usual administration of ammonium chloride, the kidney, in some measure, balances the anion excess with sodium and potassium. With the administration of resin, however, the availability of sodium and potassium for balance is small. In this instance, with the removal of sodium and potassium, ammonia production was forced to a maximum. It follows that administration of the resin to individuals with impaired renal function should be exercised with caution.

The disadvantage of oral administration of Liquonex CRW centered around the 20 to 25 size 00 capsules that had to be fed with each meal. Constipation may be experienced as the stool acquires the sandy consistency of the resin, but has so far only occurred in the subject of the balance study.

Evidence for calcium deficiency was lacking in this study but the possibility must still be considered. The evidence for potassium deficiency is stronger than for calcium and may well be a danger in the use of Liquonex CRW. Calcium and potassium occupy Liquonex CRW preferentially to sodium, an admirable characteristic for water softening for which the resin is primarily manufactured. This characteristic, however, is inherent in all cation exchange substances yet it does not

³ Patient C. G. has taken Liquonex CRW in daily dosage of 200 mEq. continuously for 10 months without clinical evidence of ill effects.

seem to invalidate its use for removal of sodium from the diet.

The limited clinical material presented here illustrates the advantages and dangers of administration of Liquonex CRW. The evident dangers are acidosis and potassium deficiency. It is far from clear how the acidosis might have contributed to the death of the patient with cirrhosis of the liver, but there may have been some indirect relationship. Excessive loss of potassium must also be considered although the electrocardiogram did not exhibit the expected pattern of potassium deficiency. The use of potassium lactate, or potassium bicarbonate in conjunction with the resin may prove to obviate these dangers without reducing the efficacy of sodium removal. Liquonex CRW, although representing an exchanger with one of the higher capacities, is by no means the ideal substance. Exchange substances of still higher capacity, exchanging ions other than hydrogen, if effective at the pH and electrolyte concentration of the intestine, would represent further advances in resin therapy.

CONCLUSIONS

1. The principle of the use of a cation exchange substance has been shown to be sound in retaining dietary sodium in the gastrointestinal tract to be excreted in the stool.

2. Its use in congestive heart failure and cirrhosis of the liver resulted in a diuresis of existing depots of fluid which did not reaccumulate while the resin was administered.

3. The undesirable characteristics of a particular exchange substance are indicated. With the use of Liquonex CRW, potassium depletion and acidosis must be considered as possible hazards.

CARBON TETRACHLORIDE POISONING IN MAN.

I. THE MECHANISMS OF RENAL FAILURE AND RECOVERY¹

By JONAS H. SIROTA²

WITH THE TECHNICAL ASSISTANCE OF HATTIE WARMBRAND

(From the Cardiovascular-renal Research Group, Mount Sinai Hospital, New York City)

(Received for publication May 6, 1949)

Carbon tetrachloride poisoning in man, whether by inhalation or ingestion, is frequently associated with anatomical and clinical evidence of renal damage. Smetana (1) has shown that the distal tubule appears to bear the brunt of the renal pathological processes resulting in oliguria or anuria, and Woods (2) has demonstrated the identity of the renal pathology in this disease with that of the crush syndrome. This type of acute renal failure has therefore been included among the subclassifications of lower nephron nephrosis by Lucké (3). This author believes that the scant urine flow in this syndrome is adequately explained by the back-diffusion of the glomerular filtrate through the damaged tubular walls. This concept was first promulgated by Dunn, Haworth and Jones (4) working with experimental oxalate nephritis. Bywaters and Dible (5) concluded this to be the mechanism of anuria in the crush syndrome on the basis of morphology alone. A. N. Richards (6) was able to observe this phenomenon directly in the frog kidney poisoned with mercuric chloride. He noted the absence of urine formation in spite of normal or augmented glomerular filtration. Additional evidence cited for the occurrence of abnormal tubular permeability is the finding of negative T_{mD} 's³ by Bobey *et al.* (7) and of decreased creatinine/inulin clearance ratios by Richards, Westfall, and Bott (8) in experimental uranium poisoning in dogs; the demonstration of negative T_{mPAH} values by Redish, West, White-

head, and Chasis (9) in a child with oliguria due to sulfathiazole intoxication and by Marshall and Hoffman (10) in two patients with post-shock uremia; and the demonstration by Phillips and Hamilton (11) of markedly reduced renal creatinine extraction ratios in dogs with near normal renal blood flow following renal ischemia.

Recently attention has been directed toward the possible contribution of renal hemodynamic factors in the maintenance of the oliguria during the post-shock phase, when the full-blown picture of uremia becomes manifest. Trueta *et al.* (12) have demonstrated in man as well as other mammalian species the presence of juxtamedullary glomeruli with large efferent arterioles draining directly into the venous circulation through the vasa recta, thereby avoiding the usual peritubular capillary circuit. As an explanation for the oliguria in the crush syndrome these authors postulate a neurogenic mechanism resulting in the shunting of blood from the active filtering and secreting cortical zone to the poorly functioning juxtamedullary region of the kidney.

Phillips and Hamilton (11) demonstrated rapid recovery of renal blood flow, as measured by the Fick principle, in dogs following two hours of complete renal ischemia. It is unfortunate that they did not perform renal blood flow studies on their dogs with three and four hours of renal ischemia, since it was these animals which subsequently developed progressive uremia, thus more nearly simulating the human material. Bobey *et al.* (7) observed immediate and maintained normal renal blood flow values in dogs with uranium poisoning for periods as long as 14 months. However, since uranium exerts its maximum toxic effects upon the proximal tubule (13) and the dose used was insufficient to cause oliguria, neither the histological nor usual clinical manifestations of the human syndrome under discussion were simulated in this series of experiments.

Corcoran, Taylor and Page (14) performed serial inulin and diodrast clearances upon one pa-

¹ Indebtedness is gratefully acknowledged to the U. S. Standard Products Co., of Woodworth, Wisconsin, for furnishing inulin in generous amounts for parenteral use in this work.

² Sarah Welt Fellow, permanent address: Department of Medicine, The Mount Sinai Hospital, New York City.

³ Abbreviations used will be as follows: D = diodrast, IN = inulin, CR = endogenous creatinine, PAH = p-aminohippurate, C = clearance, thus C_{IN} is clearance of inulin, T_{mPAH} and T_{mD} = tubular maximal excretory capacity for p-aminohippurate and diodrast respectively. E = renal extraction ratio, RBF = renal blood flow, U/P ratio = ratio of urine concentration to plasma concentration.

ith carbon tetrachloride poisoning during every phase and found values for C_{IN} , C_D of 5.8 cc./min., 67.8 cc./min. and 3.7 in. respectively on the 10th day of the

By the 64th day these values had re- the normal range. On the basis of the data these authors concluded that in ad- tubular back-diffusion depressed renal v, caused by renal swelling, plays an im- ple in the production of oliguria. Mar-

Hoffman (10), using mannitol and formed similar studies upon two cases ck uremia and one case of carbon tetra- chloride poisoning. The clearance values were all markedly depressed during the early recovery phases with a gradual return to normal. Burnett *et al.* (15) studied renal clearances in wounded soldiers. They found significant depressions of mannitol and PAH clearances and Tm_{PAH} in those patients who had suffered moderate to severe shock even though the studies were undertaken from 14 hours to 30 days after recovery from shock.

With the severe tubular damage and probable tubular back-diffusion of the test substances that occur during the early recovery phase of this syndrome it would seem that the estimation of hemodynamic factors on the basis of uncorrected clearance measurements yields data of dubious significance. Certainly when a marked decrease in the renal extraction of PAH occurs, as has been adequately shown to be the case following total renal ischemia in the dog by Selkurt (16) and Phillips and Hamilton (11), the clearance of this substance cannot be used as a significant measure of effective renal plasma flow. These limitations of the clearance methods were early emphasized by Smith (17).

We have therefore studied the renal extraction ratios of PAH and inulin together with their clearances and other aspects of renal function in four patients with acute carbon tetrachloride poisoning during various stages of the disease. The results indicate that a marked reduction in renal blood flow is in fact important in the maintenance of the oliguria, if not in its initiation.

METHODS

Studies of renal function were performed on four male patients with acute renal damage due to inhalation

of carbon tetrachloride.⁴ These studies were started between the eighth and 11th day from the onset of oliguria and continued periodically for as long as 60 to 320 days. Simultaneous inulin, p-aminohippuric acid, urea, endogenous creatinine and chloride clearances and the measurement of Tm_{PAH} were performed according to the standardized techniques of Smith, Goldring, and Chasis (18). The technique of Warren, Brannon, and Merrill (19) and Bradley and Bradley (20) was utilized for the renal vein catheterizations in order to determine the renal extraction of PAH, inulin and oxygen.⁵ Renal blood flow was calculated by the formula $RBF = (UV/A-R) \times (1.00/1.00-H)$, where A, R, and U represent arterial, renal venous and urine concentrations respectively of PAH or inulin in mgm./cc., V represents urine flow in cc./min., and H is the hematocrit expressed as a fraction of 1.00. Since repetition of renal vein catheterization in any one individual during the early recovery phase was thought unwarranted this procedure was performed once on each individual at times representing different phases of the recovery process. In each case the final position of the catheter was checked by means of roentgenograms.

On the days intervening between the standard clearance studies, when the 24 hour urine flow exceeded 1000 cc., endogenous creatinine clearances alone were obtained using two to four hour periods and voided urine specimens. One blood specimen was drawn at the midpoint of the urine collection period. In two of the subjects with severe oliguria, inulin and PAH clearances were determined, each on one occasion, by giving one intravenous injection which acted as both the priming and sustaining doses. Blood was drawn approximately every six hours and urine was collected at the end of a 24 hour period by catheterization and bladder washout. Total PAH (free and acetylated) and inulin analyses were performed on these specimens. The urine of the preceding day was used for the determination of the rate of excretion of the inulin blank (UV_0).

The other studies of renal function consisted of the usual clinical measurements for urine concentrating capacity, urinary acidity, efficiency of phenol red excretion, examination of the urinary sediment, plasma creatinine and urea nitrogen determinations and the semi-quantitative estimation of albuminuria.

Inulin was determined by a modification of Harrison's method as described by Goldring and Chasis (21), with the exception that 2 cc. of undiluted plasma were added to 6 cc. of 20 per cent yeast and 1.0 N NaOH was substituted for 1.1 N NaOH in the precipitation of proteins. PAH, both free and total, was determined by the method of Smith *et al.* (22); creatinine by the Brod and Sirota modification of the Bonsnes and Taussky method (23);

⁴ These patients were on the 1st and 2nd Medical Services of Mt. Sinai Hospital. The clinical details will be presented elsewhere.

⁵ Drs. Sigmund Brahms and Irving Kroop collaborated with the author in the performance of the renal vein catheterizations.

TABLE I
The renal extraction ratios of PAH and inulin and renal plasma flow
in four cases of carbon tetrachloride poisoning

Patient	Number of days of oliguria	Day from onset of oliguria	Renal extraction ratio $\frac{A-R}{A}$		Renal plasma flow*		Renal blood flow	$1.08 \times C_{PAH}$	C_{IN}
			PAH	Inulin	$\frac{PAH}{UV}$ $\frac{A-R}{A-R}$	$\frac{Inulin}{UV}$ $\frac{A-R}{A-R}$			
F. M.	10	8	0.034	0.00	cc./min. 24.5	cc./min. 0	cc./min. 40.8	cc./min. 0.944	cc./min. 0.00
F. H.	2**	13	0.106	0.045	160	167	232	21.4	7.84
H. Z.	11	24	0.895	0.133	640	708	896	618	97.2
W. M.	17	37	0.594	0.149	592	434	897	392	56.0

* U, A and R represent urine, femoral arterial and renal venous plasma concentrations of PAH or inulin respectively, in mgm./cc., and V represents urine flow in cc./min. These values were obtained from averages of three extraction ratios and three urine collection periods, except for F. M. in whom one urine collection period was used.

** The occurrence of oliguria is questionable in this case because of difficult anamnesis. Its duration, if present, was definitely no longer than two days.

blood oxygen by the method of Roughton and Scholander (24); chlorides by Van Slyke and Hiller's adaptation of Sendroy's method (25); and urea by the aeration technique of Van Slyke and Cullen (26). All colorimetric determinations were performed on the Coleman Jr. spectrophotometer.

RESULTS

1. Renal extraction ratios and renal blood flow

Control PAH renal extraction ratios performed on four patients without renal disease yielded values of 0.904, 0.890, 0.910 and 0.895. The values for PAH and inulin extraction ratios and the renal plasma flows calculated therefrom in the four patients with carbon tetrachloride poisoning are presented in Table I. It is evident that during late oliguria and early diuresis there was a marked reduction in renal blood flow, and that the perfused tissue extracted PAH with poor efficiency, so that $1.08 \times C_{PAH}$ yielded values much lower than $UV/A-R$ for PAH, the true renal plasma flow.⁶ Thus,

⁶ $\frac{UV}{A-R}$ represents the application of the Fick principle to the determination of renal plasma flow, and as long as a measurable quantity of PAH is present in the urine it is an expression of true renal plasma flow, being independent of the efficiency with which the tubules extract PAH from the plasma. C_{PAH} , the clearance of PAH, or $\frac{UV}{A}$ in the normal kidney is a measure of renal plasma flow to effective functioning renal parenchyma and is therefore dependent upon the efficiency of renal extraction. It normally is about 92 per cent of the total plasma flow, the remaining 8 per cent representing plasma flowing to non-functioning tissue such as capsule, interstitium and perirenal fat. Hence $1.08 \times C_{PAH}$ should

patient F. M. on the eighth day following the onset of oliguria had a renal plasma flow of only 24.5 cc./min. and his kidney extracted PAH with only 3.4 per cent efficiency.⁷ The value for $1.08 \times C_{PAH}$ was reduced to 0.94 cc./min. Patient F. H. on the 13th day had a renal plasma flow of 160 cc./min. in spite of a diuresis of over 3000 cc. in 24 hours. His PAH renal extraction efficiency was 10.6 per cent; $1.08 \times C_{PAH}$ was 21.4 cc./min. Patient H. Z. had both a normal renal plasma flow and PAH extraction ratio by the 24th day, so that $1.08 \times C_{PAH}$ closely approximated the true renal plasma flow. In contrast, W. M., who suffered oliguria for 17 days, still had a reduced PAH extraction (59.4 per cent) on the 37th day even though his renal plasma flow was normal (592 cc./min.). The low renal blood flow figures of 896 and 897 cc./min. for H. Z. and W. M. respectively are merely expressions of low hematocrits.

The use of the inulin extraction ratio for the calculation of renal plasma flow is fraught with error because of the comparatively low arterio- approximate $\frac{UV}{A-R}$ closely. A discrepancy between these values merely reflects the deviation of renal extraction of PAH from the average 92 per cent value.

⁷ Technical errors in the withdrawal of renal venous blood, such as too much suction causing the admixture of inferior vena caval blood with renal venous blood, would yield an erroneously low extraction ratio. However, this would also yield an erroneously high plasma flow, since the value $A-R$ in $\frac{UV}{A-R}$ would be smaller than the true value.

CARBON TETRACHLORIDE POISONING IN MAN

 ** These clearances were of the 24 hour type, as explained under methods.
 † The plasma and urine blanks for inulin on these days were assumed to be the same as those found on the 10th day.

venous difference, high plasma and urine inulinoid blanks and the relative insensitivity of the analytical method as compared to the PAH method. The good check in the calculations of the renal plasma flow by the two methods in patient F. H. was surprising. The poorer checks obtained in the other three subjects were expected. The C_{IN} and E_{IN} of 0.00 may be due to lack of filtration or tubular back-diffusion of the inulin molecule or a combination of both.

A urea extraction ratio determined in F. M. simultaneously with PAH yielded a value of 0.149 and a calculated renal plasma flow of 24.1 cc./min., affording an excellent check on the figure 24.5 cc./min. as obtained by means of the PAH extraction ratio.

A renal arteriovenous oxygen difference of 3.0 volumes per cent with an oxygen utilization of 26.8 cc./min. obtained in subject W. M. on the 17th day are within the normal range. The oxygen utilization was not determined in the other three patients.

2. Renal clearance studies

The results of the renal clearance studies are presented in Table II. There was a marked reduction in the clearance values of all the substances studied during oliguria and early diuresis. The following points are of special interest:

a. With the onset of diuresis the increment in the clearances of inulin, creatinine or urea were extremely small or even in the negative direction in patients F. M. and F. H. on the 10th and 12th days respectively. This suggests that the initial diuresis may be a reflection of tubular repair rather than an increase in glomerular filtration. However, since active water reabsorption appears to be markedly impaired at this stage, an increase in glomerular filtration, *per se*, of a magnitude small enough to be undetected with present methods, may result in a large increment in daily urinary output.

b. The U/P ratio for chlorides was always significantly less than 1.00, indicating preservation of selective tubular reabsorption of chlorides. During early diuresis the U/P ratio for inulin reached minimum values of 1.38 and 2.51 in patients W. M. and F. H. respectively, with simultaneous chloride U/P ratios of 0.51 and 0.20.

Since the kidney is unable to do osmotic work at this stage, the urine being isosmotic with plasma (sp. gr. 1.010), water must follow the actively reabsorbed chloride in order that osmotic equilibrium be maintained. Such low inulin U/P ratios, therefore, in the presence of considerable selective chloride reabsorption, is suggestive of abnormal back-diffusion of inulin.

c. The clearance of PAH, though reaching very low figures during the early recovery phase, was always greater than C_{IN} and C_{CR} . In addition, Tm_{PAH} values were never negative, indicating continued active tubular secretion of PAH.

d. In patient H. Z., who sustained the least renal damage as judged by recovery rate, the CR/IN clearance ratio remained close to unity between the 24th and 250th days. The other three patients revealed high CR/IN clearance ratios during the early recovery period with gradual declines towards unity as recovery neared completion.

3. Recovery of function

The recovery of the inulin, creatinine and PAH clearances and the Tm_{PAH} values together with declining plasma creatinine levels are plotted against days following the onset of oliguria for the individual patients in Figure 1.

From Figure 1 it is evident that the recovery process may be arbitrarily divided into three functional phases. The first phase was initiated with the onset of diuresis and lasted from one to eight days. In spite of diuresis the plasma creatinine concentration continued to rise for one to three days apparently because of the absence of or very slight improvement in the clearance values. The second phase, starting between the second and ninth days, was initiated by a rapid fall in plasma creatinine concentration and a rapid increase in all the clearance values, reaching 40 to 70 per cent of the expected norm by the 40th day from the onset of oliguria. During this phase the relative C_{CR} increment was greater than the C_{PAH} , which in turn was slightly greater than the C_{IN} increment. The third phase, starting from about the 40th day was associated with gradual rises in C_{IN} , C_{PAH} and C_{CR} , the lower limit of normal (80 per cent of the statistical norm) being reached between the 100th and 200th day. Except for one C_{CR} value in patient F. H. on the 220th day the clearance values remained well under 100 per

FIG. 1. INDIVIDUAL RECOVERY CURVES FOR C_{IN} , C_{CR} , C_{PAH} , T_{MPAH} , AND PLASMA CREATININE CONCENTRATIONS IN FOUR SUBJECTS RECOVERING FROM CARBON TETRACHLORIDE POISONING

Cessation of oliguria occurred in F. M. on the 10th day, in F. H. on the third day, in H. Z. on the 11th day and in W. M. on the 17th day.

* Effective renal blood flow, calculated by $\frac{C_{PAH}}{1-H}$ where H is the hematocrit expressed as a fraction of 1.00, is not recorded before the 30th day because of poor renal PAH extractions.

cent of the statistical norm throughout the period of observation. Patient W. M., who suffered the most severe functional renal damage with oliguria for 17 days, had a C_{IN} of 108 cc./min. and a C_{PAH} of 618 cc./min. on the 331st day from the onset of oliguria.

In marked contrast, Tm_{PAH} for all four patients rapidly reached high normal values in the third phase of recovery, with patient W. M. obtaining the supernormal value of 130 mgm./min. per 1.73 sq. m. by the 175th day. With the further passage of time all the Tm_{PAH} values declined, leveling off at the expected normal value in F. H. by the 132nd day, in H. Z. by the 250th day and in W. M. by the 331st day. Because of the continued relative depression of C_{PAH} and C_{IN} the ratios C_{IN}/Tm_{PAH} and C_{PAH}/Tm_{PAH} in all four subjects remained lower than normal.

There was no correlation between the speed of recovery and the number of days of oliguria or the maximum plasma concentration of creatinine or urea. Thus, patient H. Z., the most critically ill of the four because of severe pulmonary edema, who suffered marked oliguria for 11 days and had peak plasma concentrations for creatinine and urea nitrogen of 32.0 and 226 mgm./100 cc. respec-

tively, recovered most rapidly. Conversely, although F. H. had questionable oliguria for two days the renal damage sustained by him was as severe as the two with oliguria 10 and 11 days.

The sequence in which the usual clinical tests of renal function returned to normal is presented in Table III. The relatively low peak values for plasma urea nitrogen and creatinine concentrations in patient W. M. in spite of 17 days of severe oliguria is due to two runs on the artificial kidney.⁸ The time of return to normal values of the plasma urea nitrogen concentration (8 to 18 mgm./100 cc.) was from the 24th to the 36th day from the onset of oliguria; for the plasma creatinine concentration (0.80 to 1.20 mgm./100 cc.) from the 29th to the 61st day.

All four patients had proteinuria. During oliguria the urine protein concentration was roughly between 1.5 to 3.0 gms./1000 cc. in three patients. W. M. spilled about 3 to 6 gms./1000

⁸ Drs. H. E. Leiter and I. G. Kroop placed this patient on the Kolff artificial kidney for six hours on the ninth day, during which time his plasma urea nitrogen concentration dropped from 108 to 69 mgm./100 cc. A second dialysis on the 15th day caused a drop from 98 to 57 mgm./100 cc.

TABLE III
The sequence in which the clinical tests of renal function returned to normal in four cases of carbon tetrachloride poisoning

Patient	Number of days of oliguria	Plasma urea nitrogen			Plasma creatinine			Proteinuria		Specific gravity		Phenol red excretion		Day of disappearance of abnormal urine sediment

* Arbitrary maximum normal values for plasma urea nitrogen and creatinine concentrations were chosen as 18 and 1.20 mgm./100 cc. respectively.

** The occurrence of oliguria is questionable in this case because of difficult anamnesis. Its duration, if present, was definitely no longer than two days.

cc. during this stage. With the onset of diuresis the daily proteinuria gradually decreased in quantity so that by the 30th day it had disappeared in all except W. M. In the latter it did so by the 37th day. All four exhibited occasional faint traces of proteinuria for two to three months thereafter with eventual complete subsidence.

Following the onset of oliguria the urinary specific gravity gradually became fixed between 1.009 and 1.011 in all four patients and remained so for 20 to 35 days. The ability to concentrate urine to a minimum specific gravity of 1.025 after a 12 hour water fast returned relatively late, varying between 96 and 220 days.

The ability to secrete an acid urine was only slightly impaired from the onset of oliguria in three of the subjects, who had urine pH's ranging from 5.4 to 6.7. In patient W. M., however, up to the 13th day urine with an average pH of about 6.0 was passed. From the 13th through the 23rd day the urine pH ranged between 7.0 and 8.0 in spite of mild clinical acidosis. Acid urine was again excreted on the 24th day when urine with a pH of 5.5 was passed.

DISCUSSION

The marked reduction of renal blood flow during late oliguria and the early recovery phase in carbon tetrachloride poisoning may be a sequela rather than the initial cause of the renal failure. Adequate explanation for this depression of blood flow is found in the development of severe interstitial edema and inflammatory swelling of the kidneys as described by MacMahon and Weiss (27), Smetana (1), Woods (2) and Lucké (3). Unfortunately, because of the nature of the methods, it has not been possible to measure renal blood flow in man at the onset of oliguria. The experimental results of Richards (6) and Bobey *et al.* (7) with nephrotoxins suggest that renal blood flow may be normal during the initial phase of acute renal failure.

The morphological and clinical similarities of the post-shock and the nephrotoxic anurias have been well established (2, 3). The common denominator appears to be tubular injury. The occurrence in man of severe and prolonged renal anoxia during shock has been demonstrated by Lanson, Bradley, and Courmand (28), and Badenoch and Darmady (29) found identical tubular

lesions in men who died of post-shock uremia and in rabbits which developed uremia following two-hour ligation of the renal arteries. Thus, prolonged renal anoxia simulates the nephrotoxic action of carbon tetrachloride.

On the basis of the available information it is possible to formulate a working hypothesis concerning the pathogenesis of anuria and the mechanism of recovery from the acute renal failure of carbon tetrachloride poisoning. During the first 24 to 48 hours after exposure, because of nausea and vomiting, dehydration may be present. During this phase of gastro-intestinal irritation the urine, although scant, may be of normal composition and of high specific gravity. The tubules, still intact functionally, respond to the needs of the organism by maximally reabsorbing water. Between the first and third days after exposure the nephrotoxic action becomes manifest with severe oliguria or anuria and rapidly rising plasma urea and creatinine concentrations. Because of abnormal glomerular permeability considerable protein and gross blood may be present in the scant urine that is passed. Until studies of *early* anurias are performed in man we must tentatively accept the findings of the experimentalists and explain the scant urine flow of this stage by back-diffusion of the glomerular filtrate across the damaged tubule wall. "The organism urinates into the kidney instead of the bladder."² There is now convincing evidence to minimize the role of pigmented casts in the production of oliguria by mechanical blockage (3).

As oliguria progresses renal blood flow becomes markedly diminished. The resultant anoxia added to the initial toxic insult causes maximal depression of tubular function. Some of the small amount of filtrate now formed appears to be lost by back-diffusion. It is of some interest that during this phase and that of *early* diuresis, although there is fixation of urinary specific gravity and markedly depressed phenol red excretion, Tm_{PAH} and E_{PM} , the ability to retain chloride and to secrete an acid urine may be only slightly diminished.

Tests used for the secretory activity of the proximal tubular system during this phase may yield erroneously low values because of back-diffusion through the severely disorganized distal tubular

² This simile originated with Dr. Paul Klemperer.

system. Apparently carbon tetrachloride poisoning causes less injury to the proximal tubules than other circumstances leading to acute renal failure, as in all the published cases in which functional studies were performed (six including the four presented herein) Tm_{PAH} was never negative and returned to normal values with relative rapidity.

Diuresis initiates the recovery process. It occurs without significant changes in the clearance values and in the presence of low renal blood flow, and probably represents reestablishment of the tubular barrier to the indiscriminate back-diffusion of the filtrate. The rapid increase in tubular and glomerular function of the second stage of recovery is the result of tubular regeneration, diminishing renal interstitial pressure and rising renal blood flow. The gradual increase in filtration and blood flow of the third stage of recovery probably represents gradual reabsorption of inflammatory tissue and reestablishment of the finer vascular channels. Burwell, Kinney, and Finch (30) present autopsy findings of a case of renal injury three months after an episode of intravascular hemolysis, with death due to an unrelated cause, revealing cortical scarring. In a patient with acute carbon tetrachloride poisoning causing four days of oliguria who died 10 months later from an unrelated cause, Simon (31) failed to demonstrate significant renal pathology.

The high values for Tm_{PAH} obtained soon after the 40th day may represent transient compensatory hyperfunction of the proximal tubular system. The ability to concentrate urine maximally is the last tubular function to return to normal, probably representing final complete functional integrity of the distal tubule. These functional aspects of tubular recovery reflect the morphological pattern of mild proximal tubular damage and severe disorganization of the distal tubules.

Since a severe absolute reduction in renal blood flow has been demonstrated in the late oliguria of carbon tetrachloride poisoning, the shunt described by Trueta and his colleagues, if operative at the time of measurement, could not have been of great functional significance, since such a mechanism implies little reduction in total renal blood flow, but merely cortical bypassage. There has been no evidence to show that such a mechanism is responsible for the initiation of anuria in man.

All data so far available indicate that this juxta-medullary bypass is of little physiological import in normal man (32, 33), in man with increased intra-abdominal pressure (20), in essential hypertension (34) and in congestive heart failure (32, 35) by the demonstration of continued normal renal extraction of PAH in these conditions.

CONCLUSIONS

1. By means of the Fick principle the renal plasma flow was determined in four male subjects with acute carbon tetrachloride poisoning. Renal venous blood was obtained by catheterization of the right renal vein. P-aminohippurate was used as the test substance. In two of the subjects there was a marked reduction in the renal plasma flow and PAH renal extraction ratio. On the eighth day of oliguria the renal plasma flow in one of these subjects was 2.45 cc./min. and the PAH extraction ratio 0.034. On the 13th day from the onset of a questionable two-day oliguric period the second subject had a renal plasma flow of 160 cc./min. and a PAH extraction ratio of 0.106 in spite of a urine flow of over 3000 cc./24 hrs. In a third subject both the renal plasma flow and the PAH extraction ratio were normal on the 24th day. The fourth subject, who had suffered oliguria for 17 days, had a renal plasma flow of 592 cc./min. on the 37th day and a continued depression of the PAH extraction ratio to 0.594. Because of low PAH extraction ratios C_{PAH} is not a valid measure of renal plasma flow during oliguria and early diuresis following carbon tetrachloride poisoning.

2. The oliguria and anuria of carbon tetrachloride poisoning and the markedly depressed renal clearances of all substances during early diuresis are the results of a marked reduction in renal blood flow and glomerular filtration as well as abnormal tubular back-diffusion of the filtrate. It is probable that back-diffusion plays the most important role during early oliguria as decreased renal blood flow does during late oliguria and early diuresis.

3. The recovery of renal function following acute renal failure due to carbon tetrachloride poisoning is characterized by three clinical phases. The first phase starts with the cessation of oliguria and is associated with rising plasma creatinine and urea concentrations in spite of an adequate urine flow. It lasts from one to three days, during which

time there is little change in C_{IN} , C_{CR} and C_{PAH} . The second phase starts with a rapid decline in the plasma urea and creatinine levels and a simultaneous rapid rise in C_{IN} , C_{CR} and C_{PAH} which reach 40 to 70 per cent of normal by the 40th day from the onset of oliguria. The third phase, starting about the 40th day, is characterized by gradual improvement in renal blood flow and glomerular filtration, so that the lower limit of normal is reached between the 100th and 200th day. During this phase the ability to elaborate a maximally concentrated urine is recovered.

4. During the early part of recovery phases Tm_{PAH} reached high normal or supernormal values in three of the patients, ranging between 83.9 and 130 mgm./min. per 1.73 sq.m. These gradually declined to the expected norm. The ratios C_{IN}/Tm_{PAH} and C_{PAH}/Tm_{PAH} , however, were significantly lower than normal in all four patients when last determined on the 60th, 250th, 307th and 331st day, respectively, suggesting some residual vascular damage.

(Received for publication January 17, 1949)

Rahn and Otis (1) have described the normal changes in the alveolar gases during work and demonstrated the quantitative relationships between alveolar oxygen, carbon dioxide, respiratory quotient and ventilation by means of continuous recording of gas analyses. They were able to delineate the pathways of change which are controlled by the excretion of carbon dioxide, and observe the effects of hyperpnea, hypoxia, hypoventilation and CO₂ breathing as well. Pelnar (2), at first independently and later in conjunction with Rahn, observed the changes in expired air composition in normal subjects as well as in patients with cardiorespiratory impairment in relation to work. By means of a simple diagram relating the changes in O₂ and CO₂ content of expired air with the respiratory quotient during the stress of exercise, he felt that he could delineate respiratory function better than by any other means in a manner that paralleled the intensity of dyspnea in patients. Between the extremes of *a*) normal performance with a large circular curve and *b*) the abnormal performance with no change in these values during exercise, Pelnar found a series of results which were characteristic of the varied stages of dyspnea. Thus he was able to evaluate functional performance largely in terms of changes in the respiratory gases during exercise. In contrast to this are the older methods reported by Kaltreider and McCann (3) who relied chiefly on ventilation volumes and ventilation indices to appraise pulmonary capacity during work. Both Rahn and Otis (1) and Pelnar (2) express the

view that the level of ventilation is controlled in large measure by the CO₂ when breathing normal ambient air in which the strong stimulus of hypoxia is lacking. The hypoxic stimulus of breathing 15% oxygen in normals or hypoxemia from pulmonary disease in patients clearly induces greater ventilation levels, however.

With these considerations in mind we have attempted to repeat these studies in both normal subjects and patients with disease to ascertain not only the normal respiratory pathways, but also the circulatory pathways during exercise and recovery. Thus the inter-relationships between the two can be considered in a way to demonstrate how the adaptations of each complement and spare the other. The techniques employed consist essentially of controlled work-loads by means of walking on a motor-driven treadmill and continuous gas analyses of expired air as well as determinations of electrocardiographic changes in rate and pattern, blood pressure and arterial oxygen saturation (oximeter) (Figure 1). Observations have not been limited to the basal state in order to obtain an appraisal of performance to a standardized stress of exercise in relation to ordinary circumstances in regard to diet, clothing and activity. In a separate report the statistical analyses of variability of normal performances under these conditions is presented (4). For the purpose of defining the normal pathways in this report, only the mean values of all pertinent observations obtained at minute intervals before, during, and after exercise are graphically considered in relation to each other.

METHODS

Thirty-five normal adults were used for this investigation (20 men, 15 women, ranging in age from 20 to 57 years). Each was allegedly healthy and gainfully employed, and none had any detectable sequelae of any previous cardiac or pulmonary disease. All rested before

EQUIPMENT FOR EXERCISE TOLERANCE TESTING

FIG. 1

Arrangement of equipment for exercise tolerance testing. One observer remains on the treadmill platform with the patient, records blood pressure, electrocardiogram, symptoms and signs. The other observer seated at the continuous analyzer records the heart rate, respiratory rate, ventilation volume, gas concentrations, and oximeter at one minute intervals.

the test period and then were observed during 10 minutes of rest sitting in a chair, 10 minutes level walking on the treadmill at the rate of 2.6 mph (12 rpm of the conveyor belt or 70 meters per minute velocity), and again for 10 minutes of recovery while sitting in a chair. Each was lightly clothed, and the barometric pressure and temperature were the prevailing room air values (747.3 ± 1.1 mm. Hg, 0.15% coefficient of variability) and $24.9 \pm 1.9^\circ$ C (7.9% coefficient of variability).

The systemic blood pressure was obtained from an aneroid sphygmomanometer at frequent intervals, even during walking. Changes in arterial oxygen saturation, as well as variations in characteristics of the ear (green filter), were followed by an improved Millikan oximeter. Three electrodes attached to a rubber belt around the subject's chest for "ground," "indifferent" (right scapula) and "apical" contacts permitted registration of the chest lead electrocardiogram on a direct-writing instrument as well as continuous recording of the pulse from the amplified QRS spikes. Expired air gas data were obtained from a modified A-13A oxygen mask through a $1\frac{1}{2}$ inch corrugated rubber hose mixing chamber conducting to a continuous gas analyzer. Ventilation volumes were electrically recorded from a low resistance (differential pressure less than 1 inch of water) wet-test gasometer with accuracy of $\pm 1.65\%$ at 100 liter per minute velocities. The respiratory rate was recorded by activation of a variable time-delay relay counter. Gas analyses were made continuously on aliquot (saturated with water) samples (at flow rates of 100-125 ml per minute regulated by calibrated rotameters),

by means of a thermal-conductivity cell for carbon-dioxide expressed in volumes per cent; and a suitable Pauling oxygen analyzer which determined the partial pressure of oxygen. The calibration of each was established and checked against room air prior to each test. The terminal portion of each expired breath (mid-capacity air)⁵ was continuously sampled by the alternate pulsations of a very thin rubber balloon incorporated in the face piece of the mask for analyses of oxygen tension by a second Pauling analyzer and the derivation of changes in the physiological dead space. These values included the dead space of the mask which was reduced by careful packing with cotton. At the rates of flow stated above, the aliquot gas samples reached the analyzers after a lag of 10-20 seconds for expired air and 40-50 seconds for the mid-capacity air. Since the response of the CO₂ analyzer was delayed to 99% peak reading in five minutes from zero concentration, acute changes in CO₂ concentration could not be followed with accuracy. Hence no correction for inspired air volume from differences in nitrogen concentration in expired air were made, and estimates of the expired air respiratory quotients were only approximated values (averaging about 4% too high), (Figure 2).

⁵ In the traditional sense, alveolar air has the composition of that volume of air which is obtained at the end of forced expiration, hence includes in the last portion of the reserve air partition of the pulmonary capacity. "Mid-capacity" air corresponds in gaseous composition to that obtained at the end of normal expiration.

MAGNITUDE OF ERROR IN OXYGEN CONSUMPTION

FIG. 2

The differences in oxygen consumption calculated directly are compared with those obtained by correction for changes in nitrogen tension. The magnitude of error by the short cut calculation is considered almost negligible in relation to the change in oxygen consumption initiated by exercise.

The reproducibility and accuracy of gas analyses by this method was estimated as *variations* of duplicate analyses from an ideal value of zero in terms of *standard deviations* as follows:

	CO ₂ vol. %	O ₂ vol. %
a) Haldane technique	± 0.054	± 0.058
b) Continuous analyzer	± 0.160	± 0.028
c) Between "a" and "b"	± 0.360	± 0.083 °

Consequently reliance was placed upon the oxygen values. Suitable conversion tables permitted rapid determination of the volumes per cent of oxygen absorbed (respiratory efficiency) from air from the observed expired air pO₂ reading and the dry barometric pressure at the operating temperature. Similarly a factor was established for each subject that permitted conversion of the ventilation volumes observed into liters per square meter of body surface area at 760 mm. Hg and 0° C dry. The oxygen consumption was estimated from the product of the corrected minute ventilation and the respiratory efficiency and ranged between 96-101% (depending on the R.Q.) of the true value based upon corrections for nitrogen differences in inspired and expired air. All primary observations were recorded and graphed at one minute intervals (Figure 3). From these data, average values per period, dead space volumes, oxygen debt, ventilation indices, etc. were calculated.

Accessory procedures routinely employed were the determination of maximum *mask* breathing capacity by means of voluntary hyperventilation for 30 seconds at the completion of the above test, changes in oximeter

° The standard error for oxygen analyses determined by the Haldane technique was 3.3 times greater than that obtained by the Pauling oxygen analyzer.

readings with breath-holding, and estimation of lung-to-ear circulation time with the oximeter.

RESULTS

Inasmuch as *statistical analyses* showed no significant differences in the data according to the sex of the subjects, all the consecutive one minute observations for the mean values of both sexes have been compiled together. The resting values (allowing for differences in basal state, tempera-

EXERCISE PERFORMANCE (NORMAL MALE)

FIG. 3

Typical exercise performance graph of a normal male subject. The values of "11%" and "1.0" adjacent to the recovery curve for oxygen consumption refer to oxygen debt and half-time recovery time, respectively. The value of minute-by-minute observations of multiple measurements is illustrated by the fleeting changes in heart rate, ventilation, and oxygen consumption occurring on the seventh, 19th, and 28th minutes. These variations were involuntary reactions to environmental stimuli initiated by visitors during the period of observation. The subject was unaware of these variations.

FIG. 4

The rates of adaptation to changing states of activity are compared on the basis of per cent change from the preceding mean one minute values for ventilation volume, oxygen consumption, volumes per cent of oxygen absorbed from expired air and heart rate for the first four minutes of exercise and recovery. The 10th minute represents changes from standing. Note that ventilation and oxygen consumption show the greater changes first, and that the change in volumes per cent of oxygen absorbed is delayed, causing the final increment in oxygen consumption during exercise.

ture and pressure) are in accord with those reported by others.

The *rates of changes* in the observations of ventilation, oxygen consumption, respiratory efficiency (volumes per cent of oxygen absorbed) and the heart rate are shown in Figure 4. These changes are expressed as percentage changes in the several factors from the immediately preceding minute during the periods of adaptation to and from a steady state of exercise. The values for the 10th minute of observation represent the changes induced by standing up and are of smaller magnitude than those for walking. As a result of exercise both ventilation and heart rate promptly rise, but the greatest change is confined to the first minute. The oxygen consumption initially rises in proportion to the ventilatory response, but thereafter it continues to rise during the next minute because of the greater respiratory efficiency. By the 13th minute of observation all factors have approached a new and relatively stable range during the steady state of exercise. In recovery the reverse changes promptly occur, but in this

instance there are two apparent differences: *a*) there is no lag in decline of respiratory efficiency, and *b*) the heart rate is restored toward the resting level more rapidly than the other factors.

There are changes in the physiological *dead space* along with the increments in the *mid-capacity ventilation* associated with exercise (Figure 5). The latter shows an almost linear rise during the first three minutes of exercise as well as a linear decline in three minutes during recovery from exercise. During the last seven minutes of exercise there is a just perceptible increase in the mid-capacity ventilation. The slight discrepancies between total ventilation and mid-capacity ventilation appear to be related to fluctuations in the physiological dead space. On the average, throughout the three periods of observation the dead space represents 21% of the tidal volume. Both the relative and absolute values for the dead space are lower than those reported by others (about 26 to 30% [5, 6]), and recent improvements in the face mask sampling device yield somewhat higher dead space values indicating a technical error as partly responsible for these discrepancies. Although the dead space shows a

MEAN INTRAPULMONARY VENTILATION

FIG. 5

Relationships of mean intrapulmonary ventilation, physiological dead space, and tidal air volume in ambient values, B. T. P. S., in normal subjects.

FIG. 6

The mean respiratory pathways in normal subjects illustrate the various inter-relations between ventilation, oxygen consumption, ventilation equivalents for oxygen, respiratory quotient, and changes in activity from rest to exercise and back to rest again. The arrows indicate the direction of the loops, and the numbers adjacent to the loops indicate the specific minutes of observation during the testing procedure. The iso-R.Q. lines are indicated by the background grid; note that the ultimate exercise R.Q. is slightly lower than the resting value. (Inasmuch as the oxygen consumption and dead space change with activity, iso-ventilation lines cannot be applied to this graph). Note that the ventilation equivalent for oxygen is lower during exercise than at rest, indicating increased pulmonary capillary flow and more effective oxygenation of the pulmonary arterial blood. See text for further discussion.

disproportionately large value early in exercise followed by a transient decline, the average dead space value during exercise is 62% larger than the resting values.

The mean respiratory pathways of adaptation from a steady state of rest to that of exercise and the converse during recovery are shown in Figure 6. The oxygen consumption at first increases proportionately with the increments in ventilation, but a little later it rises more rapidly because of greater respiratory efficiency (volumes per cent of oxygen absorbed, or reciprocally, diminishing ventilation equivalents for oxygen). The improved respiratory efficiency is a function of more effective alveolar ventilation and circulation as well as alterations in blood flow and composition (see below). Concurrently the physiological dead space enlarges. After the 13th minute of observation (third minute of exercise), the estimated

oxygen consumption gradually declines 5% as the respiratory efficiency slowly recedes (Figure 6) with a perceptible rise in mid-capacity ventilation (Figure 5). On the average there is a 22% increase in respiratory efficiency at this level of work. The estimated R.Q. of expired air shows wide fluctuations during the adaptive phases because of the differences in rates of change in the several factors representing ventilation and circulation. The direction of change in the R.Q. is always a clockwise loop showing a low value early in exercise as the highest values for respiratory efficiency are achieved by the 13th minute of observation (Figure 6). During steady states of performance, either rest or activity, the expired air R.Q. may be considered representative of tissue metabolism throughout the body. With this level of work, the R.Q. does not rise above the resting value as it does with more severe levels of work

MEAN CIRCULATORY PATHWAYS

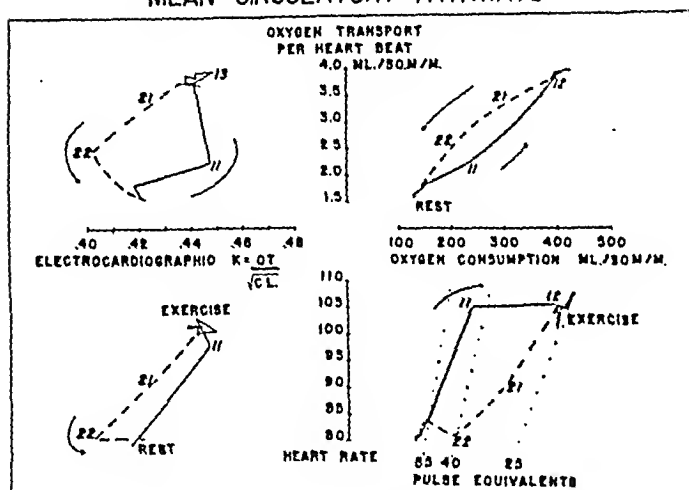

FIG. 7

The mean circulatory pathways in normal subjects illustrate the various inter-relationships of heart rate, oxygen consumption, pulse equivalents for oxygen, amount of oxygen carried per heart beat and electrocardiographic K constant during changes in activity from rest to exercise, and back to rest again. Note that the heart rate rises rapidly during the first minute, and maintains a plateau thereafter during exercise. The decline in pulse equivalents indicates a rise in stroke volume. The arrows indicate the direction of the loops, and the numbers adjacent to the loops indicate the specific minutes of observation during the testing procedure.

(7). With the onset of recovery the $R.Q.$ of expired air transiently exceeds 1.0 as retained CO_2 continues to be excreted in excess of the rate of oxygen absorption reduced with diminished tissue demands for oxygen.⁷ Simultaneously the level of ventilation is maintained above the tissue demands by the stimulus of retained CO_2 , and concurrently most of the aerobic oxygen debt is repaid.

The *mean circulatory pathways*, based upon consecutive observations of minute heart rate, oxygen consumption, oxygen transport per heart beat, and systolic time are shown in Figure 7. The systolic time is derived from the (chest lead)

⁷ Pelnar utilizes the abnormally high $R.Q.$ values during steady states of either rest or moderate activity to recognize the presence of hyperventilation, beyond the metabolic needs of the tissues, caused by neuropsychogenic factors. The usage of the term "respiratory quotient" in this sense may be unfortunate, especially when consideration is given to the limitations in accurately measuring the concentration of carbon dioxide by the present authors. Possibly the term "respiratory ratio" or ratio of carbon dioxide excreted to oxygen absorbed would be more appropriate.

electrocardiographic changes in the K constant, or observed QT interval divided by the square root of the cycle length to correct for changes due to rate. The oxygen transport is derived from the following equations:

(a) Cardiac Output

$$= \text{Heart rate} \times \text{stroke volume} \\ = \frac{\text{Oxygen consumption}}{\text{A-V } O_2 \text{ difference}}$$

and by substitution:

(b) Oxygen Transport

$$= \frac{\text{Oxygen consumption}}{\text{Heart rate}} \\ = \text{Stroke volume} \times \text{A-V } O_2 \text{ difference.}$$

The oxygen transport also represents the average rate of oxygen transfer from either alveolar air to mixed venous blood, or arterial blood to peripheral tissues, per unit of physiological time of one heart beat. Statistical analyses of rates of change in large series of observations on normal subjects show that there is a 7% increase in cardiac output for every 10% increment in oxygen consumption, and that the stroke volume shows somewhat greater increases than the A-V oxygen difference with increasing cardiac output (8). Similarly analyses of the present series of mean values shows a linear relationship of a high order of significance between oxygen consumption and oxygen transport ($r = 0.938$). With the initiation of exercise the heart rate promptly accelerates during the first minute of exercise and thereafter remains on a plateau (Figure 4). Since the oxygen consumption continues to rise, and hence the cardiac output, further increases in cardiac output must be achieved by larger stroke volumes. The rates of change in oxygen transport show the greatest increase during the second minute of exercise when the A-V oxygen difference probably is also widening due to a reduction of mixed venous oxygen content caused by blood returning from the exercising muscles (7). Concurrently the respiratory efficiency is attaining its highest and the $R.Q.$ its lowest values. During these adaptive changes in circulation (Figure 3) there are corresponding changes in the systolic time manifested by the electrocardiographic K constant. Initially with exercise there is an appreciable rise during the first minute followed by gradual fluctuations dur-

ing the remainder of exercise; on the average the exercise systolic time is 7% greater than that observed during the resting period. With recovery the K value falls during the 21st and 22nd minute of observation to 9% below the exercise range and then gradually resumes the resting value. In none of the normal subjects studied at this level of work were there any significant alterations of the QRS complexes, ST segments, or T waves, other than the effects of a more rapid rate; *i.e.*, no changes in the electrocardiogram that could be associated with possible or probable insufficiency of the coronary circulation.

DISCUSSION

The continuous recording of the heart rate electrocardiographically, ventilation volume, and respiratory efficiency of expired and mid-capacity air, as well as the carbon dioxide concentration during changes in the metabolic demand initiated by exercise greatly supplements the existing information about either ventilatory performance or alterations in gaseous composition. By these means the pathways of respiratory and circulatory adaptation to the stress of exercise can be observed in terms of degrees, as well as rates, of change in a manner that demonstrates the complementary sparing action of the several variables. Appreciable uniformity of results can be approximated by control of the work-load in proportion to the body size by means of walking on a motor-driven treadmill. These studies have not been performed under basal conditions in order to observe the responses in both normal subjects and patients with cardio-respiratory diseases under ordinary circumstances of daily activity. An analysis of the range of variability and reproducibility of results in normals and alterations presented by patients with disease will be the subject of later reports. The resting values observed by these methods are in reasonable accord with those observed by others employing the Tissot-Haldane methods (9). The pathways of responses for expired air are similar to the findings of Rahn and Otis (1) for normal alveolar pathways in exercise as well as those of Pelnar (2) for the changes in expired air composition initiated by exercise.

These studies demonstrated the following changes which regularly occur with exercise:

ventilation and heart rate promptly rise to a higher plateau, but the heart rate levels off by the second minute of exercise whereas the mid-capacity ventilation continues to increase in a linear fashion for three minutes. The R.Q. of expired air initially declines with exercise as the respiratory efficiency (denominator, or volumes per cent of oxygen absorbed) rises and overshoots the steady state value by the third minute of exercise (Figure 6). This transient change is an expression of greater alveolar ventilation and circulation (together with enlarged physiological dead space) as well as greater diffusion of oxygen into more rapidly circulating blood which has a lower content of oxygen as a result of increased muscular demand in exercise (7). The arterial oxygen saturation is maintained; hence the A-V oxygen difference widens; and since the oxygen consumption continues to rise for three minutes (and heart rate does not), there is a progressive increase in stroke volume. The striking increase in oxygen transport per heart beat during the second minute of exercise is an expression of the changes in both the A-V oxygen difference and the stroke volume since it is the product of these two factors. As the apparent circulatory lag in adaptation to exercise is corrected, the expired air R.Q. gradually rises during the further attainment of the steady state of exercise and the respiratory efficiency slowly declines; ventilation just perceptibly rises; and oxygen consumption diminishes by about 6%. These changes are considered to reflect peripheral circulatory adjustments as vasodilatation occurs to dissipate heat and slight arteriolization of venous blood from small peripheral shunts permits the mixed venous oxygen content to rise (and narrow the A-V oxygen difference) (10, 11). With these changes there is no significant change in diastolic blood pressure although the systolic pressure, and hence, the pulse pressure increase. The alterations in the systolic time expressed by the electrocardiographic K constant are considered expressions of changes in blood flow as well as contractile force and ventricular emptying associated with increased stroke volume. Some individuals exhibit slight reductions in both heart rate and ventilation about the seventh minute of exercise, indicating further adjustments in performance; possibly these changes account for the phenomenon of the "second wind"

subjectively observed at more severe levels of work.

Recovery from exercise begins at once, and in normal subjects at this level of work it is largely completed within three minutes. The first variable to approach the resting level is the heart rate which corroborates the usefulness of the recovery pulse as a measure of physical fitness (12). During this time the expired air R.Q. rises above 1.0 as retained carbon dioxide continues to be excreted, delaying somewhat the restoration of ventilation to the resting level although favoring the repayment of most of the aerobic oxygen debt.

SUMMARY

1. The mean respiratory and circulatory pathways of adaptation to the stress of exercise have been studied in 35 normal adults. The work-load was regulated by treadmill walking, and multiple observations were made continuously at one minute intervals before, during, and after the exercise.

2. The previously reported changes in gas composition were confirmed.

3. The additional values of simultaneous consideration of circulatory changes are discussed.

4. The adaptive changes in respiration and circulation are shown to complement and spare each other by the differences in time and rate of change.

ACKNOWLEDGMENT

The authors wish to acknowledge the helpful criticisms of Doctors W. S. McCann and N. L. Kaltreider of the Department of Medicine of the University of Rochester in the editing of this paper.

VARIABILITY OF RESPIRATORY AND CIRCULATORY PERFORMANCE DURING STANDARDIZED EXERCISE¹

BY ROBERT A. BRUCE,² RAYMOND PEARSON,² FRANK W. LOVEJOY, JR.,²
PAUL N. G. YU,² AND GEORGE B. BROTHERS³

(From the Chest Laboratory of the Department of Medicine of the University of Rochester School of Medicine and Dentistry and the Medical Clinics of the Strong Memorial and Rochester Municipal Hospitals, Rochester, N. Y.)

(Received for publication January 17, 1949)

In the preceding report (1) the complementary adaptations of respiration and circulation to the stress of exercise in normal subjects were described. Various isolated measurements, obtained by a method of continuous observation, were found to be in accord with those reported by earlier investigators employing the established Tissot-Haldane techniques of respiratory gas analysis. Because of the continuity of observation, various rates of change in adapting from a state of rest to a standardized stress of exercise (treadmill walking) as well as rates of recovery could be observed in relation to each other as loops of cardio-respiratory responses. These respiratory and circulatory pathways portray the representative responses in normal subjects, but a survey of the *range of variability* in normals and patients is needed before these pathways can be utilized properly for the study of impaired functions in patients with cardio-respiratory diseases. Pelnar (2) has critically reviewed the existing methods of functional appraisal of the causes of dyspnea in patients and expressed the opinion that his new method based upon the continuous study of the R.Q. curve during rest, exercise and recovery provides a more satisfactory appraisal of function in relation to dyspnea than any other method previously available. If these observations can be confirmed, then continuous observation of standardized exercise may provide the means of rating disability in relation to functional impairment of respiration and circulation and possibly differentiating between the two chief types of dyspnea in patients: pulmonary insufficiency and circulatory insufficiency.

It is the purpose of this paper to analyze statistically the data obtained from the same 35 normal

adults previously reported (1) to determine the range of normal variation for the several measurements. By this means the minimum and maximum value for each factor during rest, exercise or recovery can be determined. Secondly, the magnitudes of change in the several factors in normal subjects performing at this standardized workload are assessed in both normal subjects and patients with various diseases causing clinical symptoms and signs of functional impairment. Hence the necessary percentage change in the various exercise measurements for a significant difference in the same individual on repeated examinations was estimated. Thus the comparative value of the various measurements made can be estimated to ascertain those which are more reliable for discriminating functional impairment and rating physiological disability.

METHODS

Statistical analyses consisted of determination of the standard deviation, standard error and coefficient of variation for each of the observations in the same 20 normal males and 15 normal females previously reported in terms of mean values. The standard deviation of the mean values was calculated according to the formula

$$\sigma_m = \sqrt{\frac{\sum d^2}{N-1}}^4$$

assuming, of course, that our sample was truly a representative group. Standard error was calculated according to the formula $SE_m = \frac{\sigma_m}{\sqrt{N-1}}$,

and the coefficient of variability was calculated as $\frac{\sigma_m}{\text{mean}}$ multiplied by 100 to express all values in per cent. Because two standard deviations above and below the mean include approximately 95% of the range that can be expected on the basis of random sampling, the limits of normality are tabulated as plus or minus two standard deviations from the mean values for the periods of rest, exercise and recovery.

⁴ σ_m = standard deviation of mean; d = difference of observation from the mean; Σ = summation; N = degrees of freedom.

* Corrected for R.Q. and Oxygen Debt

Variations within each of the three periods of observation were studied similarly for the basic primary measurements of heart rate, ventilation volume, and respiratory efficiency (volumes per cent oxygen absorbed). Each item was measured at one minute intervals consecutively, and the standard deviation of the mean values was calculated for all 35 normal subjects. By this method, one thus obtains a measure of the variability of minute-to-minute analysis in any one period.

The magnitude of change from one period to another in the various factors was expressed as percentage change from the resting values during exercise and recovery.

The reproducibility of exercise performance was determined by analysis of the standard deviation of the mean value for repeated tests on the same individual. This analysis also includes seven abnormal patients upon whom repeated tests were made. Coefficients of variability were determined in this group as described above for the average heart rate, ventilation volume and respiratory efficiency, oxygen consumption, volumes per cent of carbon dioxide excreted in expired air, estimated R.Q., duration of walking in minutes, oxygen transport per heart beat and oxygen debt. All gas volumes were expressed in terms of STPD, corrected for surface area. The patients utilized for this purpose had the following clinical diagnoses: chronic pulmonary granulomatosis associated with beryllium compounds (two), bronchostenosis following organizing pneumococcal pneumonia (one), pericardiectomy for relief of constrictive pericarditis (one), coronary insufficiency following healed coronary

occlusions (two), and congenital heart disease due to pulmonary stenosis and auricular septal defect (one). The period of time for these observations ranged from one month to 12 months.

RESULTS

1. Statistical variations between normal subjects to the standardized exercise test (2.6 mph level walking for 10 minutes)

The observations on 35 normal adults are summarized in Table I in terms of mean values, standard deviations, standard errors, and coefficients of variability according to sex. There is no significant difference⁵ between sexes,⁶ and accordingly the averages for men and women for the several

⁵ A difference is considered significant when there is less than one possibility in 369 of being due to chance selection, or there is a three-fold difference between the standard errors.

⁶ The apparent difference in resting oxygen saturation is an artefact since the calibration of the oximeter is arbitrary. The ventilation index is almost significantly higher in men than women, largely because the vital capacity (used in the denominator of the formula) is slightly smaller in women. Ventilation index equals the sum of the average exercise and recovery minute ventilation values divided by the vital capacity, all expressed in volumes corrected for STPD and body surface area.

measurements are combined for purposes of all subsequent discussion. Allowing for differences in temperature and basal state of activity, the observed mean values for resting ventilation and oxygen consumption show satisfactory agreement with those reported by others using the Tissot-Haldane method of gas analysis (3). The volume per cent of oxygen absorbed (or ml. per liter of air) is in exact agreement with previously reported values (2, 3). The measurements with coefficients of variability of *less than 10%* are the estimations of the arterial oxygen saturation, respiratory quotients, volumes per cent of oxygen absorbed from either expired air or mid-capacity air, and the ventilation equivalents for oxygen. In contrast the heart rate, blood pressure, pulse pressure, ventilation volume, oxygen consumption, calories of heat production, ventilation index and vital capacity all exhibit greater variability. Many of these factors reflect changes due to emotional stimuli, and some may be slightly affected by differences in environmental temperature⁷ as well as the type and amount of clothing worn—factors which are not controlled in this study. The overall variability for all the measurements throughout the three periods of observation is about 12%.

The *consecutive one minute variations* in the heart rate, ventilation volume and expired air analysis for oxygen concentration, expressed in terms of standard deviations, are shown in Figure 1. The last of the three listed is the least variable. The standard deviations are of the same order of magnitude throughout the three periods of observation.

The *limits of normality* for the several factors studied are shown in Table II. These minimal and maximal values have been determined arbitrarily as plus or minus two standard deviations from the combined mean values for both males and females. All volume measurements are expressed at STPD values corrected for surface area per unit time of one minute. This is to facilitate estimation of the oxygen consumption by the short-cut method previously described. The respiratory gas concentrations are expressed in terms of volumes per cent to eliminate minor

differences related to daily fluctuations in barometric pressure which would be reflected in partial pressure values for oxygen. (Alveolar $p\text{CO}_2$ appears to be homeostatically regulated by ventilation and is less dependent upon barometric fluctuations.) The maximal blood pressure values are above the conventional range of 140/90 mm. Hg in part perhaps because of the erect posture, but more likely because of vasomotor responses to apprehension about the testing procedure. Since these individuals often show lower pressure values when relaxed in the recumbent position, a more liberal interpretation of significant blood pressure increments may be necessary. Similar comments apply to measurements of heart rate, ventilation volume and oxygen consumption—all of which reflect responses to anxiety. It is apparent from these considerations that much of the spread of normal variation is dependent upon psychoneurogenic stimuli which of course may operate in either normal individuals or those with functional impairment from cardio-respiratory diseases. Since there is less variation in concentrations of the respiratory gases, and rates of CO_2 excreted to O_2 absorbed per unit volume of ventilation may be a direct measure of neuropsychogenic hyperventilation, Pelnar's opinion that these measurements afford a more reliable appraisal of performance in patients with dyspnea is strengthened (2).

2. Magnitude of changes in normal subjects to the standardized exercise test

The amount of work done by this type of exercise is moderate since the average working caloric expenditures is only 2.1 times above the resting value.⁸ The magnitudes of changes caused by this amount of work are summarized in Table III as percentage differences from the corresponding resting measurements. Whereas the ventilatory reserve, respiratory quotient and ventilation equivalents for oxygen diminish somewhat during exercise, the remainder of the factors observed increase. The increments range from 1.5% for diastolic blood pressure to 193% for oxygen consumption. There is an average increase of 108% in calories of heat production, 135.5% in ventilation volume, 29.5% in heart rate, and 124.0% in oxygen

⁷ Statistical evaluation of the environment showed barometric pressure to be 747.3 ± 1.13 mm. Hg (0.15% coefficient of variability) and room temperature to be $24.9 \pm 1.9^\circ \text{C}$ (7.9% coefficient of variability).

⁸ Hard work is not performed until the metabolic rate is at least three times greater than the basal metabolic rate expressed in calories.

VARIATIONS FROM MEANS EXPRESSED AS STANDARD DEVIATIONS

FIG. 1

Minute-by-minute mean heart rates, ventilation volumes, and volumes per cent of oxygen absorbed from expired air in normal subjects, together with range of variations expressed as standard deviations from each mean value. The vertical lines for each minute represent the variation of plus or minus one standard deviation from the corresponding mean. The expired air values on the right side of the graph are in terms of volumes per cent.

transport per heart beat, which is a measure of the change in the A-V oxygen difference and the stroke volume.⁹

3. Variability of multiple exercise tests in the same individuals

Table IV presents the statistical findings obtained from the study of 17 exercise tests in normals, and 54 tests in seven abnormal patients with clinical cardio-respiratory impairment. All tests were done at the rate of 2.6 mph level walking for 10 minutes, or to the limits of tolerance for those

⁹ Any variations in blood volume, hematocrit (4), or arterial oxygen saturations are considered insignificant in relation to the magnitude of change in stroke volume and A-V oxygen difference indicated by the change in oxygen transport per heart beat.

who could not walk for as long as 10 minutes, and the data are based upon the average of the one minute observations serially throughout exercise. It will be seen that in all instances the coefficient of variability for the averages of the normals is less than the corresponding value for the averages of the abnormals, except for oxygen debt where the reverse relationship is found. The factors which exhibit the least variability for either normals or abnormals are the duration of walking ("endurance"), respiratory efficiency, heart rate, oxygen consumption, oxygen transport per heart beat, and ventilation volume. The appreciably greater variability of values for volumes per cent of CO₂ excreted and respiratory quotient are attributed to technique, since the CO₂ analyzer employed is neither as stable nor accurate as the oxygen analyzer. Hence these observations cannot be interpreted to invalidate Pelnar's claim that observations of the R.Q. and CO₂ concentration are as important and reliable as those for oxygen concentration.

From these data the limits of variation observed by this standardized exercise test for both normals and abnormals can be estimated from the coeffi-

Over-all average coefficient of variability: Normals 5%, Patients 10.2%

DISCUSSION

The variability, expressed in terms of per cent coefficients, for various respiratory and circulatory measurements has been determined by statistical analysis of the data obtained from the following: single exercise tests in 20 normal males and 15 normal females, and consecutive one minute observations of the primary measurements of heart rate, ventilation volume and respiratory efficiency, or volumes per cent of oxygen absorbed from expired air, including 17 repeated tests in normals, and 54 repeated tests in seven patients with definite disease entities. From these analyses there was no evidence of increased variability in the three primary measurements during exercise or recovery as compared with rest, and of these three, the respiratory efficiency showed the least variability. The overall average coefficient of variability for all factors of variability for each factor. Depending upon the level of significance one wishes to consider in evaluating differences in results between any two tests in the same patient, one may employ various multiples of the coefficient of variability. For example, since the range of plus or minus two standard deviations encompasses 95% of the possible values to be expected in a given representative sample, four times the coefficient of variability would approach an estimate of the range of non-significant variability for any measurement. In terms of exercise heart rate in patients with clinical disease, four times 6.5% would indicate 26% range of variation of exercise heart rate values which would be within the limits of variability. Hence a 30% change in heart rate, for the same individual, could be interpreted as being significant, *i.e.*, beyond the range of variation of patient and testing procedure.

tors considered during exercise was about 12% in 35 normal subjects, and in repeated testing of either normals or patients with disease 5% or 10%, respectively. The factors which showed the least variation were, in addition to the duration of walking, the three primary measurements mentioned above, and the secondary measurements obtained by calculation, such as the oxygen consumption and oxygen transport per heart beat. When the three measurements of ventilation volume, oxygen consumption and oxygen removal or respiratory efficiency are considered for the 35 normal subjects, the average coefficient of variability is 13% during rest and 11.3% during exercise. These values are to be compared with those of Baldwin *et al.* who found 10% variation during rest in the basal state and 17% during one minute of exercise in 92 normal subjects (3).

In view of these findings, the technique of standardizing exercise tolerance testing described is considered satisfactory for the investigations of dyspnea in clinical patients. The essence of this technique is the combination of multiple continuous observations of responses to a standardized stress of exercise. The latter is controlled automatically by treadmill walking. The rate of energy expenditure is moderate, averaging just over twice the resting value, and the duration of 10 minutes is sufficiently long to screen out patients with circulatory insufficiency. Finally since the range of variation is less than previously reported values for observations in the basal state, it does not appear necessary to have this as a prerequisite to satisfactory testing technique when problems of metabolism are not under consideration. Fur-

thermore it permits observations of respiratory and circulatory performance to controlled work-loads under ordinary conditions of diet and preceding activity for the patients studied.

SUMMARY

1. A statistical analysis of the cardio-respiratory performance of 35 normal adults to a standardized stress of activity has been made to determine the normal limits and range of variability in the non-fasting state.

2. The average coefficient of variability for the several factors observed during rest, exercise, and recovery was about 12%.

3. Similar analyses of data from multiple tests on the same individual—either normal subjects or patients with clinical disease—showed average coefficients of variability of about 5% and 10%, respectively.

STUDIES IN METHIONINE METABOLISM. II. FASTING PLASMA METHIONINE LEVELS IN NORMAL AND HEPATOPATHIC INDIVIDUALS IN RESPONSE TO DAILY METHIONINE INGESTION¹

By LAURANCE W. KINSELL, HAROLD A. HARPER, GRACE K. GIESE, SHELDON MARGEN,² DAVID P. McCALLIE,³ AND JEAN R. HESS

(From the Division of Medicine, University of California Medical School; Department of Biology, University of San Francisco; Metabolic Research Unit, University of California—U. S. Naval Hospital; and Department of Medicine, U. S. Naval Hospital; San Francisco and Oakland, Calif.)

(Received for publication March 12, 1949)

In earlier methionine studies (1), it was noted that the fasting plasma methionine⁴ levels in some patients with acute and chronic liver disease, receiving DL-methionine, tended to be markedly increased. It was not too clear in all instances whether this elevation related to the methionine administration, to the disease process, or to a combination of the two. It was definite, however, that severe liver disease in itself could account for some elevation of the fasting plasma methionine level. Over an 11-month period we have attempted further to clarify this picture.

PROCEDURES

The actual quantitative assay procedures have been previously described (2, 3). It might be emphasized here that one concept held earlier has been modified in that the normal fasting plasma methionine level varies within a very narrow range, from 0.25 mgm. per 100 cc. to 0.48 mgm. per 100 cc., with a mean of 0.33 mgm. per 100 cc. The previous concept of a wider normal range related to a longer period intervening between the obtaining of the blood sample and the preparation of the protein-free filtrate. Considerable proteolysis apparently occurs in a matter of a few hours in some plasma specimens. All determinations here reported have been performed on protein-free filtrates prepared within three hours from the time of withdrawal of blood.

The first patients and controls in this series were given 3 gms. of DL-methionine three times daily by mouth as compressed 0.5 gm. tablets, over varying periods of time. Prior to, during, and following such periods of adminis-

tration, fasting blood specimens were obtained for D- and L-methionine quantitation. In some of these individuals, urines collected over 24-hour and/or 72-hour periods were also assayed for D- and L-methionine.

When it became apparent that a striking difference existed in the methionine retention pattern between normal individuals and many patients with chronic liver damage, a standard program was set up consisting of the following procedures:

A. Studies prior to methionine administration:

1. Fasting blood specimens for plasma D- and L-methionine assay, Monday through Friday, during Week No. 1.
2. One or more three-day quantitative urine specimens during Week No. 1 for D- and L-methionine.
3. No medication of any sort during this period, except for routine "multi-vitamin" dietary supplementation in all patients,⁵ and parenteral vitamin K in those individuals with significantly low prothrombin levels. Such medication was constant throughout the entire period of study.
4. A diet high in protein, moderate in fat, and adequate in calories, was administered throughout the study. The most severe cirrhotics received a semi-liquid, high-protein, low-salt intake.

B. Studies during methionine administration:

1. On Sunday of Week No. 2, 3 gms. of DL-methionine were administered at 1:00 p.m. and 8:00 p.m.
2. Thereafter, 3 gms. of methionine were administered at 9:00 a.m., 1:00 p.m. and 8:00 p.m., daily during Weeks No. 2 and No. 3, up to and including 9:00 a.m. on Monday of Week No. 4.
3. Daily fasting bloods were obtained Monday through Friday for D- and L-methionine during Weeks No. 2 and No. 3.
4. Three-day quantitative urine specimens were obtained for methionine assay throughout this period.

C. Studies following the cessation of methionine administration:

1. After the 9:00 a.m. dose on Monday of Week No. 4, as previously noted, methionine was discontinued.
- ⁵ "Hexavitamin Tablets" (Strong, Cobb & Co., Inc.), six tablets daily.

⁴ Unless otherwise qualified, the word "methionine" will refer to L-methionine, i.e., the natural isomer.

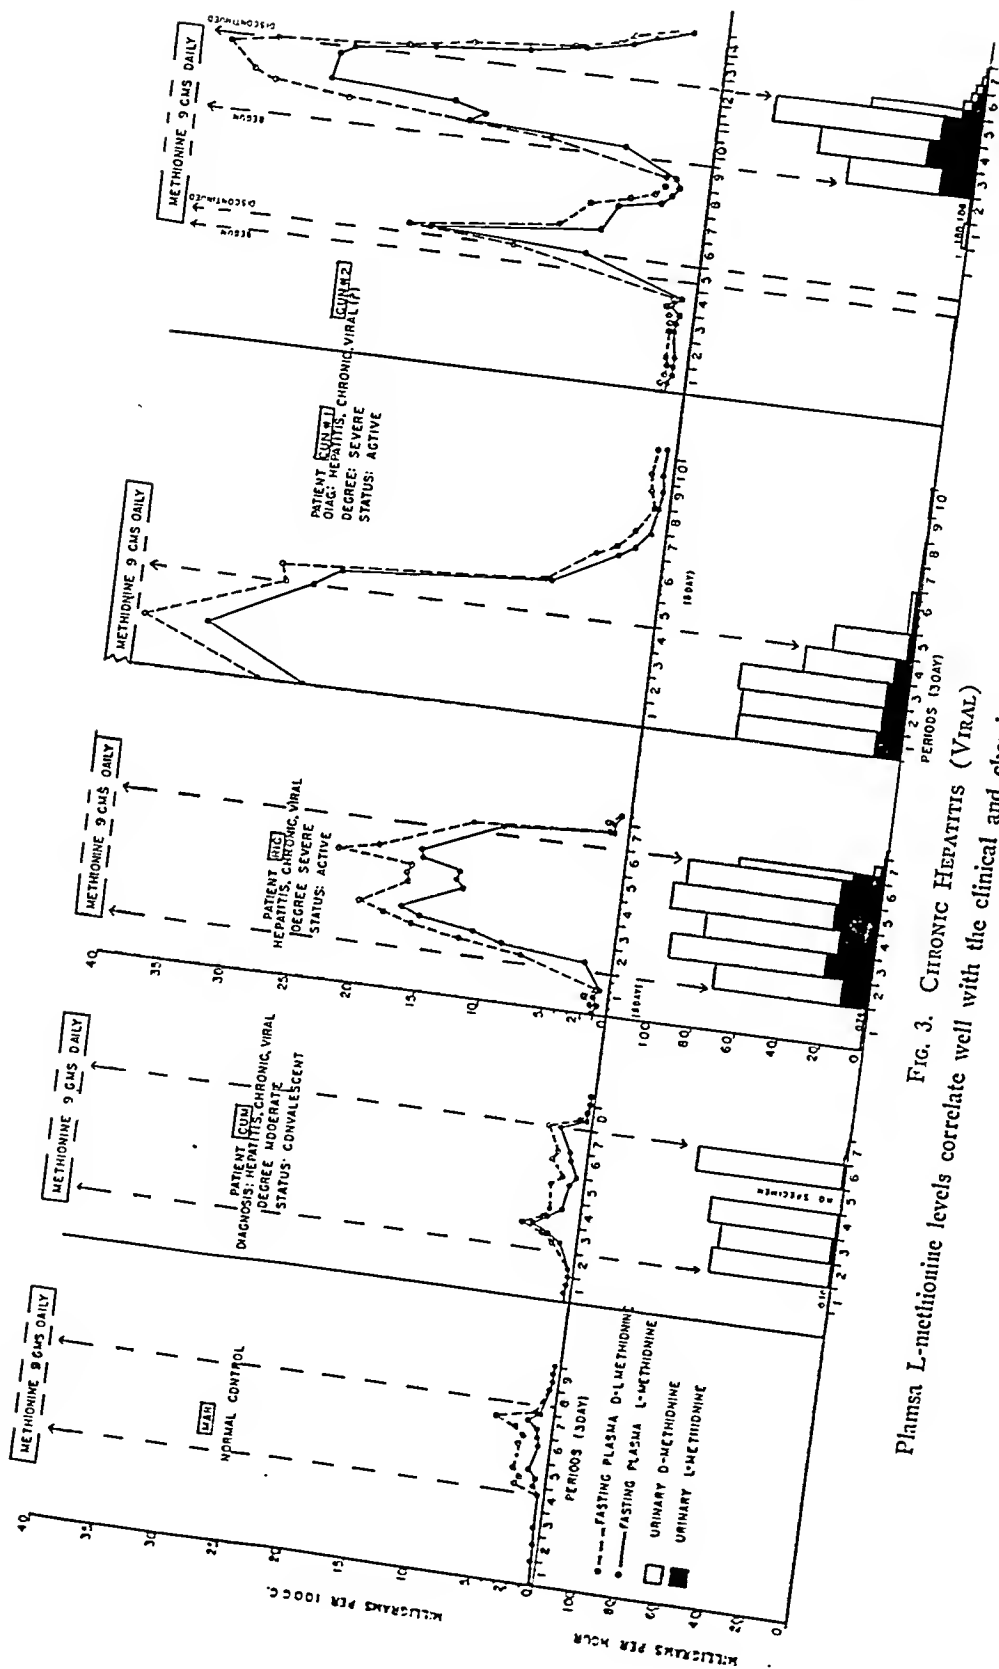

Fig. 3. CHRONIC HEPATITIS (Viral)
 Plasma L-methionine levels correlate well with the clinical and chemical evidence of hepatic insufficiency.

tion (all of the usual tests were abnormal); protein metabolism (balance studies); and liver histology (biopsy). The histological findings are those of localized areas of round cell infiltration, evidence of hepatocellular abnormality and moderate amounts of periportal fibrosis. The actual proof of viral infection is unfortunately not possible.

Patient CUM, aged 25—At the time of this study his disease process appeared to be progressively less active, as evidenced by diminution in hepatomegaly (to approximately 3 cm. below the rib margin, on deep inspiration), gradual disappearance of spider angiomas, and diminishing abnormality of liver function tests.

Patient RIC, aged 21, had had involvement of the liver for a period of one and one-half or more years, dating from an attack of acute hepatitis prior to his original admission to this Hospital. At the time this test was performed, he had major abnormality of all liver function tests including a retention of 14 per cent bromsulfalein (5 mgm. per kgm. \times 45 min.). He also had evidence of portal hypertension including some splenomegaly, and had had bleeding from an esophageal varix about two months previously.

Patient CUN, aged 50, in the spring of 1946 noted gradual onset of painless jaundice. Six weeks later he was admitted to the Veterans Hospital in San Francisco at which time he had a major degree of ascites which required eight paracenteses. He was told at that time that he had viral hepatitis.

On March 1, 1948 he had a severe hemorrhage from esophageal varices. On admission to this Hospital ten days later, he was found to have considerable ascites, an enlarged, tender liver, moderate jaundice, and abnormality of all tests of liver function above noted. He was also found to have cardiac valvular disease probably referable to an old attack of rheumatic fever.

On a high-protein, adequate-calorie diet plus complete bed rest, he rapidly mobilized his ascitic fluid and showed considerable clinical improvement and some degree of improvement in liver function, although at no time did he have complete normality of any of the liver function tests used.

From March 18 to May 13, 1948, five fasting plasma methionine values were all significantly

above the normal, the highest being 1.51 mgm. per 100 cc.

On July 9, 1948 he was placed on 9 gms. of DL-methionine daily. By July 27 he had become obviously toxic, the toxicity including some degree of disorientation and a penetrating odor which was not entirely that of methionine and which suggested the so-called "hepatic fetor." The same dose of methionine, that is, 9 gms. daily, was continued until the 2nd of August, 1948. From July 21 until August 2, he also received 9 gms. of choline chloride daily. The first methionine value shown in Study No. 1 in this patient was obtained on July 21, that is, 12 days after the institution of methionine in a dose of 9 gms. daily, and on the first day of choline chloride administration.

The second methionine study was carried on as part of a protein balance study and was instituted on October 11, 1948. His liver function tests at this time were still significantly abnormal although he no longer had any detectable ascites. The initial portion of the second study was interrupted because of the appearance of symptoms which were attributed to salt deprivation referable to a period of hot weather and low-sodium intake. When this condition was corrected the study was resumed with the results shown in Figure 3. During this second period of methionine administration, he again manifested the symptoms of major and progressive mental clouding coupled with a strong fetor which was similar to, but probably not identical with that which is commonly called fetor hepaticus.

Following the completion of this balance study, the patient was permitted to return home and was instructed to come in for a further evaluation after the Christmas holidays. Unhappily, he had a fatal hemorrhage from esophageal varices about one month after leaving this hospital and his local physician obtained no postmortem examination.

The deviations from normal of the fasting plasma L-methionine values in all three patients are quite definite, and in the last two are most striking. The degree of abnormality would appear to parallel the severity of the disease process. It is also apparent that increased urinary L-methionine appears in those individuals with very high plasma levels.

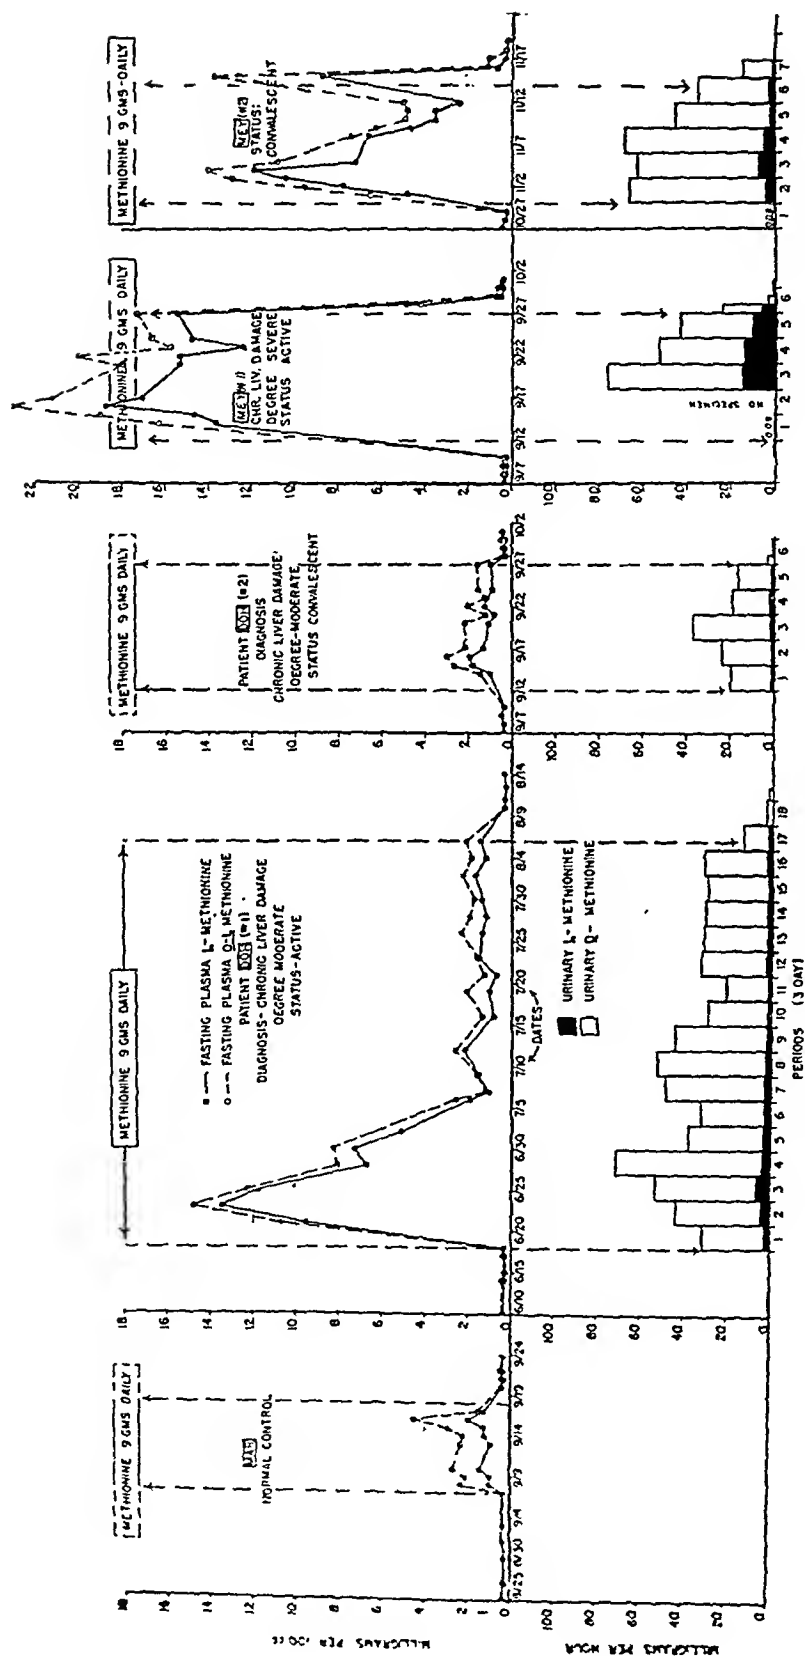

FIG. 4. CHRONIC NON-VIRAL HEPATITIS (CIRRHOSIS)

Methionine utilization improves as the liver becomes more competent.

methionine retention. He represents the only man so far with unquestionably active liver disease who has shown such a picture. It may be that hemochromatosis represents an extremely specific form of liver disease in which the utilization of methionine is not impaired. It should be noted,

however, that he was undergoing rapid clinical improvement referable to a high-protein, low-sodium intake, and hence that widespread protein tissue formation might account for such a finding.

Patient FER, aged 50, has chronic liver damage, presumably resulting from prolonged advanced nu-

FIG. 6. PROLONGED METHIONINE STUDY IN PATIENT TUC (SEVERE HEPATIC INSUFFICIENCY)

Halving the dosage still resulted in marked elevation of the fasting plasma L-methionine. "MTT" refers to intravenous methionine studies (1).

tritional deficiency (he was a prisoner of war of the Japanese for four years). In addition to clinical and chemical evidence of moderate hepatic insufficiency, he has evidence of portal hypertension in terms of recurrent hemorrhages from esophageal varices and a considerable degree of splenomegaly. His plasma L-methionine pattern is similar to that seen in patients with moderate chronic liver damage.

One additional study (Figure 6) is included on a man with very severe cirrhosis, chiefly because of the length of the study and the fact that the dosage of methionine was diminished by one-half at one stage. It will be noted in this patient, TUC, that with reduction in dosage a temporary fall in the plasma methionine level occurred, but that with the continuance of the smaller dose a rise approaching the previous levels was obtained. The one high value on the dosage of 9 gms. of methionine was not entirely comparable with that observed in other individuals on the same dosage inasmuch as this fasting level was obtained as part of an intravenous methionine study and related to a discontinuance of orally administered methionine for a 48-hour period prior to the test. It is probable that had the fasting level been obtained without any such two-day interval, the value would have been higher than that noted in any other individual included in this report. The figure is presented chiefly to demonstrate that even moderate dosage of methionine in individuals with extreme degrees of hepatic insufficiency results in fasting blood levels which are quite unphysiologic.

DISCUSSION

From the preceding observations, it is apparent that many patients with liver damage are unable properly to utilize methionine, and that such impairment of methionine metabolism is no longer present when the liver damage disappears (in patients with acute hepatitis) or has become quiescent (in individuals with cirrhosis).

If one compares the abnormalities in plasma methionine in patients with liver disease with the blood sugar findings in diabetics, there appears to be some analogy. The individual with

severe liver disease has a high fasting plasma methionine level without previous methionine administration. The abnormality in methionine metabolism in the patient with mild or moderate liver damage is only apparent when stress is applied. In our experience thus far, a spontaneously high fasting level is always correlated with a prolonged, difficult convalescence, whether the disease be viral hepatitis or "cirrhosis."

The possible mechanisms of impairment in methionine utilization provide material for speculation. Three metabolic pathways are normally open: (1) Incorporation of the methionine into protein tissue; (2) demethylation with resultant homocysteine formation; and (3) oxidation of the methionine molecule with resultant excretion of the oxidized sulfur as urinary inorganic sulfate. It appears probable that the block occurs in (1) or (2), inasmuch as the excretion of urinary sulfate is considerably increased in some of the patients with high plasma methionine levels. Simultaneous quantitation of plasma cysteine will help to rule in or out the presence of block in the methionine \rightarrow homocysteine \rightarrow cysteine sequence. Such studies are under way at the present time.

Also in the process of evaluation is the determination of methionine utilization in patients with non-hepatic disease. Should a high degree of specificity for liver disease be found, it is conceivable that the procedure may have some clinical applicability.

The appearance of a reproducible picture of toxicity in patients whose ability to utilize methionine is impaired, suggests the need for caution in the indiscriminate use of this material as a therapeutic agent in individuals with liver disease. It is probably best to regard dietary methionine as the logical source of the amino acid in such patients.

SUMMARY

Daily administration of 9 gms. of DL-methionine to patients with liver damage results in a significant elevation of the fasting plasma L-methionine, as compared to normal controls; such abnormal retention disappears when the hepatic status reverts to normal.

In some patients with severe liver damage, continued administration of methionine results in toxic manifestations.

PROTAMINE (SALMINE) SULPHATE, HEPARIN, AND BLOOD COAGULATION

By A. FRANK PORTMANN AND WILLIAM D. HOLDEN

(From the Laboratory of Surgical Research, Western Reserve University, and University Hospitals, Cleveland, O.)

(Received for publication March 24, 1949)

The availability of standardized preparations of heparin and their widespread clinical use in the treatment of thromboembolism have prompted us to reinvestigate the action of protamine sulphate on the coagulation of blood and its use as an antagonist to heparin.

For the past three decades the coagulation mechanism of blood has been represented by two equations (1):

An enormous amount of investigative work performed within the past few years has effected numerous modifications in these two equations. The present concept of the coagulation mechanism consists of a system of circulating proteins and other macromolecules exhibiting complex inter-relationships and antagonisms which become imbalanced during the process of coagulation. The results of experiments with individual protein inter-actions call upon the biochemist, physiologist, and clinician for concise interpretation and critical evaluation, and then upon repeated experimentation before conclusions can be accepted as fact for either theoretic or practical consideration.

The present investigation of protamine sulphate began as a clinical problem, but it was realized early that interpretation of the results depended upon concepts of the coagulation mechanism which are controversial. The purpose of this paper is to present a series of *in vivo* and *in vitro* experiments which extend the existing knowledge of the action of protamine sulphate on the coagulation mechanism.

EFFECTS OF SALMINE ON THE NORMAL CLOTTING MECHANISM

Effects of in vivo injections of protamine sulphate on clotting times of whole blood samples subsequently obtained

At the onset of this project, little was known concerning the possible toxic or side reactions of protamine when it was administered intravenously in normal non-heparinized patients.

It has been demonstrated (2) that large doses of protamine administered intravenously in the dog resulted in the formation of multiple thrombi (emboli). In these experiments on humans, therefore, 10 mg. of protamine were initially given and the dose progressively increased to 100 mg. For one hour following the intravenous injection, the blood pressure, pulse, and respiratory rate were recorded at 10-minute intervals. The coagulation time of the blood was determined by the Lee-White method before injection and at 10, 20, and 60 minutes afterward. Blood specimens were drawn from a three-way stopcock through which a slow intravenous infusion of normal saline was given during the course of the experiments. This was done to minimize the introduction of tissue thromboplastic substance into the test tubes. The stopcock was back washed with normal saline after the withdrawal of blood or the injection of heparin or protamine. The heparin in most instances was administered in the contralateral arm. Twenty seconds after clamping the infusion tube, a saline washed 5 ml. syringe was filled with blood and a stop watch started. Three saline rinsed 11 mm. test tubes were immediately filled with 1 ml. of blood. Coagulation was complete in each tube when the blood failed to flow on tilting with light tapping. The clotting times of the second and third tubes were averaged for recording. All determinations of clotting time were performed by the same technician. Results of these experiments are shown in Table I.

Topical application of protamine

Two dogs were anesthetized with intravenous sodium pentobarbital and areas 1 cm. square were abraded on the skin, liver, gastric serosa and mu-

cosa. Bleeding from these areas was unaffected by the topical application of protamine when compared to adjacent control areas. Jorpes *et al.* (3) stated that protamine did not act as a local hemostatic agent in heparinized patients.

Effects of protamine on in vitro clotting systems

Whole blood

The effect of protamine on the clotting time of whole blood was observed by adding 2 ml. of whole blood immediately after withdrawal to increasing amounts of protamine sulphate. The clot-decelerating action of protamine is demonstrated in Table II. In all *in vitro* experiments the pH

was 6.5 – 7.5 and the temperature 25° C. unless otherwise stated.

Fibrinogen-thrombin mixtures

Ferguson (4) previously pointed out a clot-accelerating effect of protamine when it was incubated with thrombin prior to the addition of fibrinogen. His work was corroborated. Experiments were then instituted to determine the effect of protamine on thrombin-fibrinogen mixtures in the presence of inactivated serum. Serum was inactivated by heating to 56° C. for 10 minutes in a water bath. Following inactivation, the serum was tested for fibrinogen, thrombin, and prothrombin by adding respectively thrombin, fibrinogen, and a mixture of calcium chloride, thromboplastin, and fibri-

* To each tube containing protamine sulphate was added: .1 ml. human inactivated serum + 5 u. thrombin + .85% NaCl to constant volume. After five minutes' incubation of the mixture, 1.65 mg. fibrinogen were blown in and the clotting time determined.

† NC = No clot.

‡ End point of clot formation indefinite.

nogen. No trace of fibrinogen, thrombin, or prothrombin was found. Serum inactivated in this manner does contain the heparin cofactor or substrate that heparin activates. This has been demonstrated elsewhere (5). Experiments were also set up to determine whether the five-minute incubation period produced any significant inactivation of the thrombin by the natural antithrombic activity of the serum. Control experiments, those with an incubation period of one minute and those with an incubation period of 11 minutes, produced clotting times of 12–13 seconds, on the addition of fibrinogen. Incubation periods beyond 10 minutes gave rise to more prolonged clotting times, up to 63 seconds after one hour of incubation.

There was no demonstrable accelerating effect of the protamine in tubes 2–5 (Table III). The

concentration of protamine in these tubes corresponded generally with that necessary to effect neutralization of .01 mg. of heparin *in vitro*. This is demonstrated subsequently in Table VII. In concentrations greater than this (tubes 6 and 7, Table III) there was a slight but significant reduction of the clotting time. Quantities of protamine greater than 2 mg. in this mixture (tubes 8 and 9, Table III) had a decided anticoagulant effect. In these two latter tubes, the ratio of protamine to fibrinogen was 2.4:1 and 3.6:1, and it will be shown that the inactivation of fibrinogen by the protamine produced this anticoagulant action.

Fibrinogen precipitation

Jaques (6) has shown that the protamine-heparin complex behaves according to the law of mass action, and he was able to demonstrate an equivalence point using whole dog blood. An excess of either heparin or protamine caused prolongation of the clotting time. The antithrombic (7-9) and antiprothrombic (10) action of heparin in the presence of a cofactor has been demonstrated, but the clot-decelerating action of protamine in whole blood is less well understood. According to Mylon *et al.* (11), protamine will precipitate plasma fibrinogen, and they suggested that its principal anticoagulant effect obtains by means of this precipitation. Protamine in concentrations of 1.5 mg., and 10 mg./ml. of plasma will precipitate 80 per cent and 100 per cent of the plasma fibrinogen respectively. In order to study this effect, the experiment displayed in Table IV was performed.

The addition of thrombin in reaction 2, Table IV, to the supernatant fluid without the development of a fibrin clot in 30 minutes indicates that the supernatant fluid from reaction 1 either has no fibrinogen in it, or if it is present it is bound to

‡ Ratio P/F = protamine/fibrinogen.

the protamine. When less than 6 mg. of protamine were used in reaction 1, a firm fibrin clot resulted from reaction 2. Reaction 3 precludes the destruction of thrombin by the supernatant fluid. Reactions 4 and 5, however, indicate that fibrinogen must have been present in the supernatant fluid and that in the presence of serum, dissociation of a protamine-fibrinogen complex presumably occurred and liberated sufficient fibrinogen to permit the formation of a fibrin clot. According to the mass action law, a higher concentration of protamine would further suppress the presumed dissociation of a protamine-fibrinogen complex and eventually result in complete fibrinogen precipitation even in the presence of serum. This is shown in Table V.

The approximate ratio of protamine to fibrinogen for complete inactivation in reaction 1, Table IV, was .7:1, while in the presence of serum the ratio is 1.25:1. Similarly, in plasma, the ratio is 2.5:1 (11). The ratio for whole blood has not been determined, but from the protamine to heparin titration tables, it appears that in tubes containing a protamine excess insufficient to inactivate all the fibrinogen the anticoagulant action could not be dependent on the partial inactivation of fibrinogen, since the clotting time is not necessarily a function of fibrinogen concentration. It will later be shown that the tubes containing a slight excess of protamine will not clot on addition of fibrinogen. Thus it was felt that the inactiva-

tion of fibrinogen was not the only acting anticoagulant action of protamine sulphate.

The above reactions were obtained with inactivated and active serum. The serum used did not clot within 20 minutes on addition of thromboplastin, calcium, and fibrinogen. Dissociation of the protamine-fibrinogen complex did not occur in solutions of thromboplastin or calcium chloride.

Character of the anticoagulant action of protamine, with special reference to antithromboplastic effects

Protamine may act as an antithromboplastin (12, 13) or an antiprothrombin (4, 12). To investigate these actions a series of *in vitro* experiments were carried out using whole blood. A quantity of protamine was used that would produce less than complete fibrinogen inactivation (Table VI).

Inactivation of the fibrinogen did not prevent clotting of the mixture of blood, sodium chloride, and protamine in tube 2 (Table VI) because the addition of an excess of fibrinogen in tube 3 had no significant effect. Further, the appearance of a normal fibrin clot in tubes 4 and 6 after the addition of thrombin showed that quantities of fibrinogen adequate for normal coagulation were present in solution. The results in tubes 7-12 indicated

that protamine interfered with the conversion of prothrombin to thrombin except in the presence of an excess amount of thromboplastin. The conversion of prothrombin to thrombin is inhibited but not destroyed.

PROTAMINE-HEPARIN ANTAGONISMS

The treatment of thromboembolism with heparin is widely accepted at the present time. Although serious accidents from injudicious use of heparin are decidedly uncommon, they do occur and will become more frequent as heparin is more generally used and as preparations prolonging the anticoagulant effect of heparin are developed. Chargaff and Olsen (14), who reported the neutralization of heparin by protamine in 1937, recognized its potential clinical application, but until recently protamine has been used more in experimental than clinical medicine.

The toxicity of large intravenous doses of protamine has been demonstrated in rabbits (15), rats (2), mice (16), dogs (17), and guinea pigs (18). Jaques *et al.* (19), in 1938, and more recently Parkin and Kvale (18) and Cowley and Lam (20) showed absence of toxicity in dogs when smaller but effective doses were used. Jorpes (3), using up to 60 mg. of protamine intravenously, in 1939 demonstrated the antagonism of protamine (clupein) for heparin in humans. Allen (21) has given 2.5 mg./kg. in man without ill effects.

Different preparations of protamine vary in their capacity to neutralize heparin. The protamine used in these experiments was Lot No. 8738 obtained from the Upjohn Company.

Effect of intravenous protamine on heparinized patients

Time intervals, controls, and blood specimens were identical with those described previously. The three-way stopcock method of obtaining blood was utilized.

Fifty mg. of heparin¹ were administered intravenously after a preliminary clotting time had been done. Ten minutes later, the protamine in doses of 10, 30, and 50 mg. was given intravenously. In each instance, the anticoagulant ef-

¹ Abbott Laboratories.

FIG. 1

effect of heparin was significantly reduced but not eliminated completely. Briefly, in 10 minutes 100 mg. of protamine produced approximately a 50 per cent decrease in the anticoagulant action of 50 mg. of heparin. The results in four cases are shown in Figure 1.

Protamine-heparin neutralization in whole blood

In order to verify the protamine-heparin ratio and investigate further the anticoagulant properties of protamine *in vitro*, titrations were carried out using normal blood. The same patient was used in all experiments.

Heparin, protamine, and normal saline were placed in

a clean dry test tube. Two ml. of freshly drawn blood were added to each tube and the clotting time determined by formation of a visible clot in the cork-stoppered tubes. At low heparin and protamine concentrations, the end point of coagulation was readily apparent, but in high concentrations some clot formation was evident before the entire solution was coagulated. The stop watch was started when blood first appeared in the syringe. Table VII shows the titrations.

The protamine-heparin ratio at neutralization is somewhat higher in the more concentrated mixtures, Titrations No. 2 and No. 3, but these compare favorably with the serum titrations. Although the higher concentrations of protamine would never be encountered *in vivo*, the zone of maximum neutralization is nicely demonstrated. This occurs because, except near the equivalence point, a relatively large excess of heparin or protamine is free to exert its anticoagulant action. In the latter two titrations, the difference between the control coagulation time and the coagulation time at neutralization is widened. In tube 9, Titration No. 1, the experiment was repeated using isotonic sodium sulphate instead of sodium chloride in a concentration corresponding with that in tube 10, Titration No. 3, and no significant change in the clotting time occurred. It may be presumed, therefore, that the concentration of the sulphate ion in tube 10, Titration No. 3, did not account for the elevated clotting time. No satisfactory explanation for this latter observation is apparent.

Effects of protamine on heparin plus the serum heparin cofactor, tested on thrombin-fibrinogen mixtures in vitro

Experiments were carried out to determine the protamine-heparin ratio that would effect neutralization of the latter in the presence of the serum heparin cofactor. A thrombin-fibrinogen mixture was used. Inactivated serum, previously referred to, was used in order to eliminate any antithrombin, antithromboplastic, or fibrinogen inactivating effect of the protamine. Serum inactivated by heating at 56° C. for 10 minutes does not lose significant amounts of its heparin cofactor activity (5). Titrations are shown in Table VIII and Figure 2.

The addition of the protamine to the heparin first or to the serum first did not alter the final clotting times. Under normal circumstances over 90 per cent of the thrombin incubated with the serum and heparin will be destroyed in five minutes (5). The coagulation time of the system depends, in the absence of protamine, on the thrombin remaining after its partial destruction by the antithrombic activity of serum cofactor activated by heparin. An 18:1 ratio of protamine to

FIG. 2

heparin effected neutralization in repeated titrations. Increasing the ratio to 200:1 resulted in a slightly greater decrease in the coagulation time.

Action of thromboplastin on in vitro clotting of whole blood in the presence of an excess of heparin or protamine

Experiments were set up to extend the observations made in Table VI on the effect of protamine and heparin on whole blood *in vitro* in the presence of an excess amount of thromboplastin. It had been noted in other experiments using recalcified plasma that the incubation of protamine with thromboplastin did not reduce the clot accelerating effect of the thromboplastin alone. Tubes 1, 4, 7, and 14, Titration 2, Table VII, were repeated. After observing no clot for two hours an excess of thromboplastin was added to each tube. No clot occurred in tubes 1, 4, and 7, but tube 14 clotted in 70 seconds. In tube 14 the heparin had apparently been neutralized and coagulation was inhibited by the excess of protamine which was overcome by the thromboplastin added.

DISCUSSION

There has been no observation in the literature to the effect that the intravenous administration of protamine will produce a shortening of the clotting time of the blood. Chargaff (14) reported that he was able to confirm the observation of Waldschmidt-Leitz and collaborators (22) that protamine had an inhibiting effect on blood clotting

in vitro, but in dogs intravenous doses up to 11 mg./kg. failed to show any deviation of the clotting time from controls. Chargaff (23) later found that protamine did not alter the coagulation time of chicken plasma. Jaques (6) added protamine (.017 to 1.0 mg.) to 1 ml. of dog blood and demonstrated an anticoagulant effect with the higher concentrations. Cowley and Lam (20) reported a decreased coagulation time in a dog 30 minutes following 200 mg. of protamine, but no such effect was encountered with smaller quantities of protamine. The results of the experiments reported in this paper show a slight clot-accelerating "tendency" after the intravenous administration of protamine. Although the clotting times were performed with the utmost care in all experiments, it is our belief that technical variations account for the difference in clotting times between the controls and the protamine experiments. The only conclusion that can be arrived at, in accordance with the views of other investigators in this field, is that the intravenous administration of protamine has no clot-accelerating action in the absence of heparin.

The clot-decelerating effect of protamine on whole blood *in vitro* was demonstrated in Table II. In these experiments, there was no significant effect on the addition of protamine as long as the concentration of protamine corresponded to that found in whole blood after the intravenous administration of 100 mg. or less. As the protamine concentration *in vitro* is increased, however, there is a progressive prolongation of the clotting time. Although protamine in sufficient concentration will prevent clot formation by inactivating fibrinogen, the progressive prolongation of the clotting time in these experiments was not due to such inactivation since in few of the tests did the concentration of protamine in 2 ml. of whole blood attain high enough values. Since the rapidity with which coagulation occurs depends to a great extent on the amount of thrombin present, it appears that the anticoagulant effect of the protamine in these experiments was due to impaired thrombin formation.

Mylon, Winternitz, and de Sütö-Nagy (11) demonstrated that protamine will precipitate fibrinogen. The experiments performed and indicated in Tables IV and V demonstrate that protamine precipitates fibrinogen but in addition forms a

soluble fibrinogen-protamine complex that in the presence of inactivated serum makes available sufficient fibrinogen to allow coagulation on the addition of thrombin. When the concentration of protamine is increased, dissociation of the fibrinogen-protamine complex is inhibited and coagulation prevented. When referring to the effect of protamine on the second stage of coagulation, we prefer to use the term "protamine inactivating effect on fibrinogen" rather than "protamine precipitating effect."

Experiments listed in Table VI suggest that protamine interferes with the conversion of prothrombin to thrombin in whole blood except in the presence of an excess amount of thromboplastin. Tubes 2, 7, 8, and 12 indicate that the interference with the conversion of prothrombin to thrombin by the protamine is not an antithromboplastic effect. Conclusions beyond these cannot be drawn without determining the effect of protamine on a clotting system containing purified prothrombin.

The *in vivo* effect of protamine on heparinized patients duplicated the results of previously reported observations by others and needs no comment. It should be stated, however, that any clinician using protamine to neutralize heparin *in vivo* should be thoroughly acquainted with the character and strength of the protamine preparation he is utilizing. Preparations may vary considerably in their capacity to neutralize heparin. It also appears that the neutralization of a certain quantity of heparin *in vivo* may require considerably less protamine than is necessary for neutralization *in vitro*.

The neutralization of heparin by protamine in whole blood *in vitro* is listed in Table VII. Neutralization was effected with a protamine-heparin ratio of approximately 16:1. The protamine used in these experiments was Lot No. 8738 (Upjohn). A preparation subsequently obtained (Lot No. 8960 Upjohn) showed an *in vitro* protamine-heparin ratio of 0.7:1.

The neutralization of heparin was also determined in an isolated clotting system containing fibrinogen, thrombin, the serum heparin cofactor, heparin, protamine, and saline (Table VIII). Neutralization was complete at a protamine-heparin ratio of 20:1, which agrees satisfactorily with the 18:1 ratio observed in whole blood (Table VII). It is apparent from the observa-

tions made in these experiments plus those made from the same isolated system without the addition of heparin that protamine has no significant effect upon the heparin cofactor.

SUMMARY

1. Protamine sulphate administered intravenously in doses up to 100 mg. in humans has no effect upon the clotting time of whole blood.

2. Protamine sulphate had no effect as a local hemostatic agent in dogs.

3. In relatively low concentrations in inactivated serum, protamine has a clot-accelerating effect on a thrombin-fibrinogen mixture after incubation of the thrombin with protamine.

4. The antagonism to heparin was demonstrated *in vitro* and *in vivo*. In the presence of serum or whole blood, the protamine-heparin ratio at neutralization was 18:1. An excess of either caused prolongation of the coagulation time.

5. When present in whole blood in concentration insufficient to cause complete inactivation of fibrinogen, the anticoagulant effect of protamine is due to its interference with the conversion of prothrombin to thrombin. This antiprothrombic effect is not apparent in the presence of an excess of thromboplastin.

6. An antithromboplastic action of protamine sulphate could not be demonstrated.

7. Protamine does neutralize the serum heparin cofactor.

THE EFFECT OF THEOPHYLLINE ETHYLENE DIAMINE ON RENAL FUNCTION IN CONTROL SUBJECTS AND IN PATIENTS WITH CONGESTIVE HEART FAILURE¹

By JAMES O. DAVIS² AND NATHAN W. SHOCK

(From the Section on Cardiovascular Diseases and Gerontology, National Heart Institute, National Institutes of Health, Bethesda, Maryland, and the Baltimore City Hospitals, Baltimore)

(Received for publication February 26, 1949)

The importance of a renal factor in the pathogenesis of peripheral cardiac edema has been emphasized in recent publications (1-11). The work of Fitcher and Schroeder (1) indicated that the renal excretion of salt and water was impaired during cardiac decompensation. Numerous other workers (4-6, 10, 11) reported a reduction in renal blood flow, glomerular filtration rate, and sodium excretion in cases of cardiac failure. These studies resulted in the formulation of two principal hypotheses to explain the retention of sodium and water; namely, (1) low glomerular filtration rate, and (2) more complete reabsorption of sodium and water. More recently, Wesson, Anslow, and Smith (12) have suggested that the low filtration rate delivers a sodium load to the distal tubule which is less than the T_m for sodium and leads to more complete distal tubular reabsorption of sodium.

The purpose of this investigation was to study the renal mechanism of sodium and water excretion in cardiac failure by observing the effect of theophylline ethylene diamine (T.E.D.) on filtration rate, effective renal plasma flow, and sodium clearance. Since the results of preliminary experiments suggested that T.E.D. not only increased the tubular load of sodium but also decreased sodium reabsorption, the relationship between tubular load and excretion of sodium could not be determined. However, the simultaneous measurement of filtration rate and sodium clearance during the control periods in patients with

cardiac failure afforded an opportunity to study the degree of correlation of these functions under resting conditions. Since the evidence for the mechanism of xanthine diuresis in man is conflicting (4, 11), an extensive study of control subjects was made.

MATERIALS AND METHODS

Subjects

Male subjects were selected from the wards of the the Baltimore City Hospitals and Infirmary (Home for the Aged).

Control subjects were chosen on the basis of a history, physical examination, chest roentgenogram, and urinalysis; cases with hypertension, cardiac and renal diseases were excluded. Although they were selected irrespective of age, most of them were over 50 (range = 36 - 78, mean = 60). All subjects were on a regular diet without salt restriction.

The patients in congestive heart failure were selected on the basis of clinical findings characteristic of cardiac decompensation. The majority had experienced repeated episodes of cardiac failure. Individual protocols are as follows:

Case 1, C. M. A 63-year-old colored male was readmitted with congestive heart failure for the third time on 10/30/47. When renal function was studied on 2/26/48, physical examination revealed a pulse of 88, a blood pressure of 132/84, and a respiratory rate of 30. He was dyspneic, orthopneic, and edematous. Moist râles were present at both lung bases. A harsh systolic murmur was audible at the apex. An X-ray of the chest revealed generalized cardiac enlargement and pulmonary congestion. An electrocardiogram showed myocardial disease and a tendency toward right axis deviation. The diet was regular. Treatment consisted of digitalis and mercupurin; the last injection of mercupurin was nine days prior to the experiment.

Case 2, J. P. A 43-year-old white male entered the hospital with cardiac decompensation for the third time on 3/5/48. Five weeks prior to the present admission he discontinued digitalis; signs of left and right heart failure ensued. On the day of the renal function studies, 3/8/48, physical examination revealed a pulse of 80, a blood pressure of 120/88, and a respiratory rate of 22.

¹ We are indebted to Clifford Grant, Jr., Carol Fisher, Margaret McCollom, Elsie Beard, Patricia Nichols, Georgia Proferes, Patricia Skinner, Janis Parsons and Jesse Yaffa for technical assistance. Dr. James Birren offered suggestions concerning the statistical treatment of the data. Dr. H. E. Harrison offered many helpful criticisms.

² Present address: Cardiovascular Clinic, U. S. Marine Hospital, Baltimore, Maryland.

He was dyspneic and orthopneic, and râles were present at both lung bases. A harsh, apical, systolic murmur and a localized, apical, mid-diastolic murmur were present. An X-ray of the chest revealed cardiac enlargement with a typical mitral configuration and pulmonary congestion. An electrocardiogram showed auricular fibrillation, myocardial disease, and right axis deviation. He received a Karrell diet, and 2 cc. of mercurpurin were given two days before the experiment.

Case 3, A. W. A 39-year-old colored male entered the hospital with cardiac failure for the seventh time on 3/17/48. Physical examination on the day of the experiment 3/22/48 revealed a pulse of 100, a blood pressure of 120/80, and a respiratory rate of 32. He was dyspneic and orthopneic. Moist râles were present throughout the lower portion of both lungs. A loud, harsh, moderately high-pitched, systolic murmur and a short, low-pitched, pre-systolic murmur were audible at the apex. An X-ray of the chest revealed cardiomegaly with a mitral configuration and pulmonary congestion. An electrocardiogram showed left bundle branch block, myocardial disease, and ventricular premature contractions. The liver was enlarged; ascites was present; but pitting edema of the lower extremities was minimal. He received a regular diet, and on 3/18/48, 2 cc. of mercurpurin were given.

Case 4, R. P. An 82-year-old white male entered the hospital from the infirmary for the first time on 4/28/48 because of dyspnea of several weeks' duration. When the experiment was performed the following day, physical examination revealed a pulse of 96, a blood pressure of 210/100, and a respiratory rate of 28. Râles were present at both lung bases. An X-ray of the chest revealed left ventricular enlargement with pulmonary congestion. The second aortic sound was accentuated; no murmurs were heard. An electrocardiogram showed

myocardial disease and left axis deviation. There was pitting edema of the lower extremities. The diet was regular. He had not received treatment for cardiac failure.

Case 5, F. B. A 76-year-old white male entered the hospital from the infirmary on 2/28/48 with dyspnea of two months' duration. On the day of the experimental study, 3/1/48, physical examination revealed a pulse of 84, a blood pressure of 160/95, and a respiratory rate of 20. The eyegrounds showed evidence of arteriosclerosis. The radial and brachial arteries were thick and tortuous. Râles were present at both lung bases. The chest was emphysematous, and the heart sounds were faint. No murmurs were heard. A chest film revealed cardiac enlargement, the aorta was elongated and tortuous, and calcification was noted in the aortic knob. An electrocardiogram showed auricular fibrillation, left bundle branch block, myocardial disease, and left axis deviation. The lower extremities were markedly edematous. He had been on a regular diet and had not received therapy for cardiac failure.

Case 6, B. S. The patient was a 76-year-old white male who had been in the chronic hospital for several months with mild cardiac decompensation. When renal function studies were performed on 3/4/48, physical examination revealed a pulse of 80, a blood pressure of 160/60, and a respiratory rate of 20. The eyegrounds showed evidence of arteriosclerosis. Localized plaques were palpable in the radial arteries. Râles were present at both lung bases. The heart was enlarged to the left anterior axillary line. A loud systolic murmur was heard over the entire precordium, and an aortic diastolic murmur was transmitted to the apex. An electrocardiogram showed right atypical bundle branch block, myocardial disease, and ventricular premature contractions. There was pitting pedal edema. The serologic test for

syphilis was positive. Treatment had consisted of 2 cc. of mercurpurin weekly; no digitalis was taken. His last injection of mercurpurin had been on 2/27/48. His diet was regular.

Experimental procedure

The test was begun after a 12-hour fast at 8:00 a.m., and three control clearance periods were usually completed by 9:30 a.m. Each subject was given 100 cc. of water at 6:00 a.m., and every one-half hour thereafter until the control periods had been completed. Filtration rate and effective renal plasma flow were measured by inulin and diodrast clearance respectively (13). All tests were made at constant blood levels of inulin and diodrast, using an infusion rate of 3.0 cc. per minute. Urine samples were collected by catheterization over 10-12 minute periods.

Venous pressure was measured by the method of Moritz and von Tabora and was referred to a point 10 cm. from the back at the level of the fourth intercostal space adjacent to the sternum.

Experimental Design—Control Subjects

A preliminary study (Experiments I and II) was conducted to determine a satisfactory time schedule and dose of intravenous T.E.D. Experiment III served as the control series for the study of patients in cardiac failure.

Experiment I. The effect of a single injection of T.E.D. on renal function with interruption of clearance periods during the injection. At the completion of three control clearance periods of 10-12 minutes each, 0.48 gm. of T.E.D. was administered intravenously over a period of five minutes. At the end of the injection, the bladder was washed, and five more clearance periods were fol-

lowed. Only inulin and diodrast clearances were determined in the nine subjects of this experiment.

Experiment II. The effect of the continuous administration of T.E.D. on renal function. In order to increase the magnitude of the effect, a larger dose (0.96 gm.) of the drug was given in this experiment. A single injection of 0.48 gm. of T.E.D. was administered intravenously during the first five minutes of period 4 and another 0.48 gm. was infused with the inulin and diodrast solution during the remaining five clearance periods. In this group of six subjects, sodium excretion was studied in addition to the clearance of inulin and diodrast.

Experiment III. The effect of a single injection of T.E.D. on renal function without interruption of the clearance periods during the injection. On the basis of the results of Experiments I and II, a single injection of 0.48 gm. of T.E.D. was made during the first five minutes of clearance period 4 in ten subjects. Inulin, diodrast, and sodium clearances were determined.

Experimental Design—Patients in Congestive Heart Failure

Experiment IV. The same time schedule and dose of T.E.D. as in Experiment III (control group) were used in the study of the six patients in heart failure.

Chemical Methods

Inulin analyses were made according to the method of Harrison (14). A modification of the method of Flox, Pitesky, and Alving (15) was used in the determination of diodrast iodine (16). It was demonstrated that T.E.D. did not interfere with the chemical recovery of inulin and diodrast iodine from human plasma. So-

dium was determined gravimetrically according to the method of Butler and Tuthill (17).

RESULTS

Control subjects

(Experiments I, II, III)

Glomerular filtration rate. Administration of T.E.D. was followed by a sustained elevation of the glomerular filtration rate which persisted for 55–60 minutes in the control subjects (Tables I and II) (average control period—period 8; $t = 3.64$, $P < 1\%$, $N = 10^3$ for Experiment III). The magnitude of the rise varied with the dose of T.E.D. so that the greatest increase occurred with the continuous infusion of 0.96 gm. (Experiment II).

Effective renal plasma flow. The response of effective renal plasma flow to T.E.D. was variable. In some cases, a transitory rise was observed during the fourth clearance period only; during the remaining periods effective renal plasma flow was at a control level or below. In other subjects, renal plasma flow increased during the fourth clearance period and gradually returned to the control value during periods 5–8. The average change for 10 subjects (Experiment III) was an elevation during the fourth period only (Table II, Figure 1) (average control period—period 4; $t = 5.64$, $P < 1\%$, $N = 10$) (average control period—period 8; $t = .78$, $P > 90\%$, $N = 10$). After continuous infusion of 0.96 gm. of T.E.D., the elevation in effective renal plasma flow was consistently maintained for a longer period than after a single injection.

Filtration fraction. The average filtration fraction remained unchanged during the fourth and fifth clearance periods but increased significantly

in the remaining three periods (6–8) (average control period—period 5; $t = 1.34$, $P = 90\%$, $N = 10$) (average control period—period 8; $t = 5.15$, $P < 1\%$, $N = 10$). Wide individual differences in response were observed.

Urine flow. Average urine flow increased threefold immediately after the administration of T.E.D. (average control period—period 4; $t = 6.62$, $P < 1\%$, $N = 10$) and gradually returned to a level slightly above the control values in the remaining periods (average control period—period 5; $t = 4.77$, $P < 1\%$, $N = 10$) (average control—period 8; $t = 1.44$, $P = 80 - 90\%$, $N = 10$).

Sodium clearance. The average sodium clearance (Experiment III) increased approximately threefold for 55–60 minutes after the administration of T.E.D. (average control period—period 4; $t = 6.72$, $P < 1\%$, $N = 10$) (average control period—period 8; $t = 8.72$, $P < 1\%$, $N = 10$). The mean plasma sodium values for the 10 cases were 139.7, 139.1, 139.5, 138.3, 138.8, 137.9, 139.2, and 137.9 m.eq./L. for clearance periods 1–8 respectively. The difference between the average control value for plasma sodium and the average for the five periods after the injection of T.E.D. was insignificant ($t = 2.58$, $P = 4\%$, $N = 10$). The concentration of sodium in the urine remained unchanged during the fourth clearance period but increased gradually during the remaining periods until it doubled the control value (average control period—period 4; $t = 0.70$, $P > 90\%$, $N = 10$) (average control period—period 8; $t = 3.65$, $P < 1\%$, $N = 10$).

Venous pressure. Venous pressure decreased from a mean control value of 10.0 to 8.3 cm. of saline after the administration of T.E.D. ($t = 9.08$, $P < 1\%$, $N = 10$).

Patients in congestive heart failure

(Experiment IV)

The six cases in this experiment included two patients with inactive rheumatic valvular disease, two with arteriosclerotic heart disease, one with hypertensive cardiovascular disease, and one with syphilitic and arteriosclerotic heart disease. The findings from the study of two of these cases which illustrate the variation in the control values and the response in renal function to T.E.D. are compared with the average values for the control

³ Since all values obtained before and after the administration of T.E.D. in a given subject are highly correlated, all tests for significances were made by calculating t scores by the difference method.

$$t = \frac{\frac{\sum(x_1 - x_2)}{N}}{\sigma_{\text{Mn diff.}}} = \frac{\text{Mn diff.}}{\sigma_{\text{Mn diff.}}}$$

$$\sigma_{\text{Mn diff.}} = \frac{\sigma_{\text{diff.}}}{\sqrt{N - 1}}$$

$$\sigma_{\text{diff.}} = \sqrt{\frac{\sum(x_1 - x_2)^2}{N} - \left(\frac{\sum(x_1 - x_2)}{N}\right)^2}$$

where x_1 and x_2 are observations made before and after treatment in the same subject.

group (Experiment III) in Figure 1. The results for the entire group are summarized in Table III.

Control periods. The mean values for the three control clearance periods for filtration rate varied from normal to more than 50% below normal. Effective renal plasma flow was reduced below 300 cc./min./1.73 sq.m. in all cases. Filtration fraction was elevated in all but Case 6. Sodium clearance was reduced considerably below the mean value for the control group (2.28 cc./min. \pm .23) in Cases 1-4 but was elevated in Cases 5 and 6. Attention is called to the fact that a low sodium

clearance was present in cases with a normal filtration rate while the cases with an elevated sodium clearance showed a low filtration rate. Urine flow was diminished below the average control level in all but Case 5. The concentration of sodium in urine was lower than the average control level in all but Case 6.

Periods after the administration of T.E.D. The response in renal hemodynamics and sodium excretion to this drug was variable both in magnitude and duration. The elevated filtration rate was not sustained throughout the experiment in a single case and was increased for one period only

* Injection of 0.48 gm. of drug during the first five minutes of the fourth clearance period

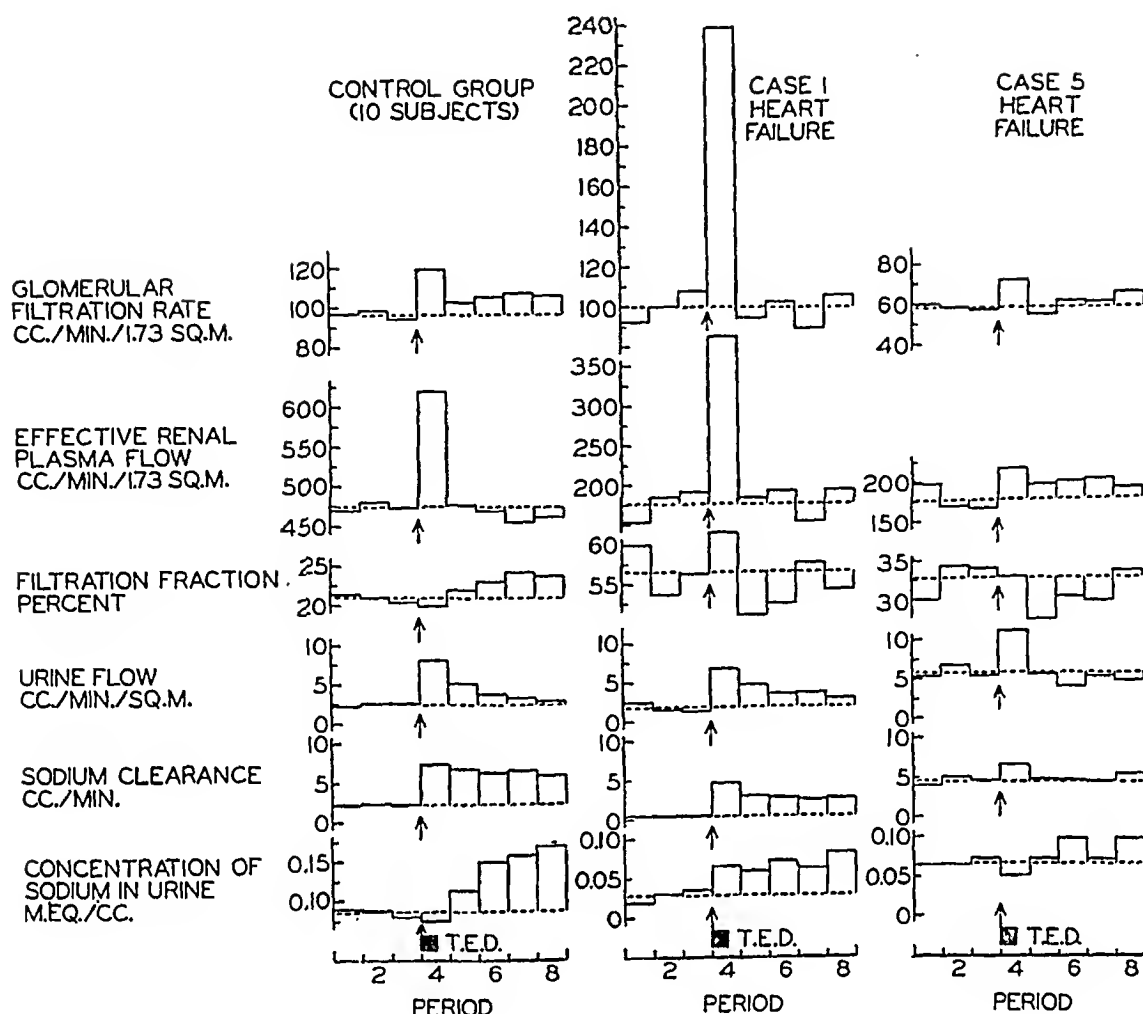

FIG. 1. THE EFFECT OF THEOPHYLLINE ETHYLENE DIAMINE ON RENAL FUNCTION IN A GROUP OF 10 CONTROL SUBJECTS (EXPERIMENT III) AND IN TWO PATIENTS WITH CONGESTIVE HEART FAILURE (EXPERIMENT IV)

Case 1 with heart failure showed a normal filtration rate but sodium clearance was low during the control periods; a maximal response to T.E.D. occurred. Case 5 with heart failure showed a low filtration rate but an elevated sodium clearance was obtained during the control periods; a minimal response to T.E.D. occurred. The arrows indicate the time of the beginning of the injection of T.E.D. The dotted line represents the mean value for the three periods before T.E.D.

in two of the three cases in which a significant response occurred. The rise in effective renal plasma flow was also transitory. The increase in sodium and water excretion varied from a moderate elevation in Case 4 to a marked rise in Cases 1 and 3. As in the control study (Experiment III) the elevation in sodium clearance was sustained for five clearance periods in Cases 1-4 but was increased during period 4 only in Cases 5 and 6. The water diuresis was maintained throughout the experiment in Cases 1-4 as compared with the more transitory diuresis in the controls. The concentration of sodium in the urine increased after T.E.D. in Cases 1-4 and remained at the elevated level in accordance with the sustained in-

crease in both urine flow and sodium clearance. In Cases 5 and 6 the changes in the concentration of sodium in the urine were insignificant.

DISCUSSION

Mechanism of xanthine diuresis

Studies of the diuretic action of xanthines have yielded conflicting findings both in lower animals and man. As a result, two principal theories have been formulated to explain the mechanism of xanthine diuresis. First, it has been proposed that diuresis is primarily the result of augmented glomerular filtration rate secondary to an increase in renal blood flow. Secondly, investigators have

presented evidence that xanthines exert their action on the renal tubules to decrease reabsorption of water and electrolytes.

Effect of xanthines on renal hemodynamics. In lower animals, some xanthines increase filtration rate, while others do not. For instance, Schmitz (18) reported that euphyllin consistently increased glomerular filtration rate in dogs while others (19-21) found renal hemodynamics unaltered significantly after the injection of theophylline in rabbits and dogs.

In man the results have been more uniform. With the exception of an early report by Blumgart and associates (22), studies (11, 23-27) have demonstrated repeatedly an alteration in renal hemodynamics. However, there is considerable variation in the magnitude and duration of the response.

In the present study, a sustained increase in glomerular filtration rate occurred consistently in the 25 control subjects while the response in patients with congestive heart failure was variable. In normal subjects, Howarth and associates (28) reported a 35% increase in cardiac output which lasted for 10-15 minutes after the intravenous administration of 0.48 gm. of T.E.D. Consequently, the sustained elevation in glomerular filtration in control subjects may be explained on the basis of renal arteriolar dilatation, while the marked initial response in Experiments II and III may be the result of a transitory elevation in cardiac output superimposed upon alterations in the renal arterioles. The more transitory response in filtration rate in patients with cardiac failure suggests that T.E.D. has less effect upon the renal arterioles in these patients than in controls. Furthermore, the marked immediate elevation and transitory response in glomerular filtration in some cases with cardiac failure (Cases 1 and 2) may be primarily the result of increased cardiac output rather than renal arteriolar dilatation.

Since most of the control values of renal plasma flow in elderly subjects are low when compared with the values reported for the middle and young age groups (16, 29), the question arises as to the completeness of renal diodrast extraction. From the available data this question cannot be answered and renal plasma flow has been referred to as "ef-

fective renal plasma flow." An increase in diodrast clearance may be indicative of an increase in renal plasma flow after the administration of T.E.D. unless the renal diodrast extraction ratio is increased by improving the cellular function of the tubules so that they extract a higher percentage of diodrast. The changes in effective renal plasma flow may then be attributed to possible alterations in (1) cardiac output, (2) afferent and efferent arteriolar size, and (3) diodrast extraction.

Effect of T.E.D. on tubular reabsorption. Consideration of the temporal relationship of the response in filtration rate to the rise in sodium clearance reveals that both were sustained for 50-60 min. in the control subjects. However, Cases 1-4 with congestive heart failure showed a very transitory or no increase in filtration rate while sodium clearance was maintained at an elevated level throughout the experiment. This finding that T.E.D. decreases sodium reabsorption was presented in a preliminary report by Davis and Shock (27) and confirmed by Sinclair-Smith and associates (11).

Evidence that T.E.D. results in decreased water reabsorption is suggested from the relationship of the level of filtration rate to urine flow in the control subjects. The elevated filtration rate was maintained for five periods after T.E.D. but urine flow returned to the control level during periods 7 and 8 (Figure 1). Since the tubules possess the capacity to reabsorb the increased load of water imposed by the elevated filtration rate during periods 7 and 8, the increase in urine flow during periods 4-6 may be explained on the basis of T.E.D. inhibiting water reabsorption.⁴ Furthermore, urine flow was maintained at an elevated level in cases of cardiac failure in whom the response in filtration rate was transitory. These findings indicate that the sustained diuretic effect of T.E.D. is primarily the result of its action (direct or indirect through the posterior pituitary) on renal tubules. The lack of an elevated urine flow in the presence of a high sodium clearance (periods 7-8) indicates that this level of sodium excretion was insufficient to effect an appreciable osmotic diuresis.

⁴ This assumes that T_m for water remains constant for periods 4-8. For a discussion of T_m for water see Wesson, Anslow, and Smith (12).

Renal Function in Congestive Heart Failure

Clearance determinations during the control periods revealed a normal glomerular filtration rate in the presence of a low sodium clearance in Cases 1-4. In Case 4, the glomerular filtration rate of 68.4 cc./min./1.73 sq.m. may seem abnormally low for even an 82-year-old man, but this is the same order of magnitude as reported by Davies and Shock (29) for men 80-90 years of age who showed no evidence of cardiac or renal disease from history, physical examination and urinalysis. Cases 5 and 6 showed a low filtration rate but sodium clearance was higher than the mean value for the control group. These findings of the lack of correlation between the level of filtration rate and sodium clearance coincide with the results of other studies (10, 11, 30) and indicate that filtration rate is not the primary mechanism for salt retention in cardiac failure.

The incidence of a normal filtration rate in one-half to two-thirds of the patients with cardiac failure in this series may be unusually high. However, examination of the results of other investigators indicates that a normal filtration rate is not uncommon (4, 10, 11, 30). Farnsworth and Krakusin (30) reported one of two cases and Sinclair-Smith and associates (11) found one of three cases who consistently showed a normal filtration rate during long term electrolyte balance and renal function studies. Briggs and coworkers (10) noted a glomerular filtration rate above 105 cc./min./1.73 sq.m. in three of 16 cases. When account is taken of the decline in filtration rate with age (29), the per cent of reported cases with a normal glomerular filtration rate in a large series such as Merrill's becomes significant.

The two cases (5 and 6) who showed an elevated sodium clearance are unusual. Certain data suggest that they had intrinsic renal tubular disease before the onset of congestive heart failure. After the state of cardiac compensation had improved, concentration tests revealed a low maximal specific gravity of the urine (1.015 and 1.018). In both cases an advanced degree of generalized arteriosclerosis was present. Although it is not possible to predict the extent of renal involvement from the degree of arteriosclerosis in the peripheral vessels, arteriosclerosis would offer a likely explanation for such renal involvement. It seems unlikely that an elevated

sodium intake was present in these two patients since they were on a diet similar to the control subjects and two of the patients with a low sodium clearance. Furthermore, the elevated sodium clearance was not the result of improvement during diuresis as described in some cases of Threefoot, Burch, and Reaser (31) because these patients were becoming progressively more decompensated before the experiment. It may be of some significance that the control subjects and patients in cardiac failure received normal saline in both the priming and sustaining solutions. Since they received approximately 3 cc. of normal saline per minute, .426 m.eq./min. of sodium chloride was infused. This value is of the same order of magnitude as the quantity of sodium excreted (.639 and .366 m.eq./min. in Cases 5 and 6 respectively).

The experimental alteration of renal hemodynamics in heart failure by T.E.D. proved to be of little importance in studying the mechanism of salt and water retention. Since T.E.D. decreases tubular reabsorption of sodium, it tends to obscure any close correlation which might exist between sodium excretion and the tubular load of sodium. It should be pointed out, however, that an elevation in glomerular filtration rate was frequently unaccompanied by a corresponding increase in sodium clearance. In other words, the tubules were capable of reabsorbing approximately two and one-half the tubular load of sodium during period 4 as compared with periods 5-8 (see Case 1).

Since the evidence presented in this study offers no support for the hypothesis that salt retention is the result of a low filtration rate, the theory that renal impairment in cardiac failure is related to tubular dysfunction should be investigated more thoroughly. A low filtration rate may lead to salt retention by increasing tubular reabsorption of sodium or by some other mechanism in some patients but in other cases the kidney retains sodium in the presence of a normal glomerular filtration rate. The exact mechanism responsible for the accumulation of salt and water in heart failure awaits a more complete understanding of the tubular reabsorptive mechanism of sodium in normal individuals. Investigation of the role of extra-renal factors such as extracellular fluid volume, adrenal cortical hormones, and the secretion of the posterior pituitary may help to clarify this complicated problem.

SUMMARY

The effect of theophylline ethylene diamine on renal function was studied in 25 control subjects and in six patients with congestive heart failure. Venous pressure was measured in 10 of the control subjects and in four of the patients with cardiac failure.

In the control subjects, an increase in filtration rate was sustained for 50–60 minutes. The response in effective renal plasma flow varied from a transitory elevation lasting 10–12 minutes to an elevation followed by a gradual return to the control level or below. Filtration fraction was usually unchanged during the first two periods after T.E.D. but was elevated during the remaining three clearance periods. Urine flow trebled immediately after the injection of T.E.D. and gradually returned to a value slightly above the control level during the next 50 or 60 minutes. Sodium clearance increased threefold and remained elevated throughout the test. The concentration of sodium in the urine was unaltered immediately after the injection of T.E.D. but gradually increased to a level double the control. The mean decrease in venous pressure was 17 per cent of the control value.

During the three control periods the patients in congestive heart failure showed a filtration rate within normal limits in Cases 1–4 while effective renal plasma flow was consistently reduced. Urine flow was below the level for the control subjects in these four patients. In Cases 5 and 6, both filtration rate and effective renal plasma flow were greatly diminished. Urine flow was elevated in Case 5 but depressed in Case 6. Filtration fraction was elevated in all but one of the six patients. The concentration of sodium in the urine was decreased below the value for the control group in all but one case.

The response in renal hemodynamics to T.E.D. in patients with cardiac failure was variable. Filtration rate and effective renal plasma flow failed to increase at all in some patients and increased over 100 per cent in others. In Cases 1–4 urine flow and sodium clearance varied from a slight to a marked response. In Cases 5 and 6 urine flow and sodium clearance increased slightly only immediately after the injection of T.E.D. The concentration of sodium in the urine increased

immediately after T.E.D. in Cases 1–4 but remained unchanged in Cases 5 and 6 except for a slight increase during the last clearance periods. The response in venous pressure to T.E.D. varied with the height of the initial level; in patients with a control tension of approximately 10.0 cm. of saline the response was similar to that observed in control subjects while one patient with a high venous tension before T.E.D., showed a marked fall.

CONCLUSIONS

The mechanism of the diuretic action of T.E.D. in man is apparently two fold. An increase in the excretion of sodium and water is associated with (1) an elevation in glomerular filtration rate, and (2) a decrease in renal tubular reabsorption of sodium and water. Although a quantitative evaluation of the relative importance of each of these factors cannot be made from the available data, it seems that a decrease in tubular reabsorption contributes more to the sustained diuresis than augmented filtration rate.

The evidence from this study offers no support for the concept that salt and water retention by the kidney in patients with congestive heart failure is the result of low filtration rate. Consequently, it appears that the mechanism of renal impairment in cardiac failure is to be sought in a study of the tubular reabsorptive mechanism of sodium.

ELECTROPHORETIC STUDIES OF THE SERUM PROTEINS IN BILIARY CIRRHOSIS

By KENNETH STERLING¹ AND WILLIAM E. RICKETTS

(From the Frank Billings Medical Clinic, Department of Medicine, The University of Chicago, Chicago, Ill.)

(Received for publication June 8, 1949)

Although the serum proteins in diseases of the liver have been studied by the electrophoretic method by many investigators, few references have been made to biliary cirrhosis (1-3). Since a systematic study has not as yet appeared, the present investigation of ten cases of obstructive biliary cirrhosis was undertaken.

METHODS

Electrophoretic runs were performed with standard apparatus and technique, the experimental details having been reported previously (4). The buffer was sodium diethylbarbiturate (veronal) of pH 8.6 and ionic strength 0.1.

In the estimation of the fractions as per cent of the serum proteins both ascending and descending patterns were used, the areas being divided by ordinates from the nadirs between peaks to the base line. The quantities of the fractions as grams per cent represent the products (4, 5) of the percentages and the total proteins from the conventional Kjeldahl method, using a nitrogen factor of 6.25. Such a method of computation involves the assumptions that the specific refractive increments and the nitrogen contents of the various protein fractions are identical. These assumptions which have been generally employed as first approximations must be modified somewhat in view of the quantitative studies of Armstrong and colleagues (6, 7). In practice the errors thus introduced appear ordinarily no greater than others inherent in the electrophoretic method. However, where there is considerable increase in the lipids associated with the beta-globulin complex, the nitrogen content of this fraction is low in comparison with its refractive increment which determines the size of the peak in the electrophoretic diagram. In such a circumstance, which occurred in some of the cases of the present series, the errors in computing the absolute concentrations of the protein fractions may become appreciable. On the other hand, the accuracy of the values for the relative proportions of the fractions (as per cent of the serum proteins) should not be seriously affected.

The tests of hepatic function were performed by the usual methods as previously described (4), alkaline phosphatase being reported in Bodansky units. Cholesterol

and cholesterol esters were determined by the method of Schoenheimer and Sperry (8).

Ether extraction of the serum was carried out in one case by performing three extractions with redistilled diethyl ether, shaking thoroughly before each separation. The procedure was carried out in a cold room at 4° C. The ether layer acquired the coloration of the serum, the hue being progressively less intense on successive extractions so that in the third, the ether layer was almost colorless.

CASE MATERIAL

The present study comprises ten cases of obstructive biliary cirrhosis. In all patients cholelithiasis had been present and cholecystectomies had been performed. All had been intensely jaundiced or were still jaundiced at the time of study. In six cases (L. S., L. H., K. V., M. G., W. H., and T. O.) development of biliary cirrhosis followed cholecystectomy, and four of these patients (L. S., L. H., W. H., and T. O.) had subsequent laparotomies in the attempt to repair a severely stenosed common duct. In four cases (F. F., M. E., M. F., and C. M.) biliary cirrhosis was already present at the time of cholecystectomy and hence could not be attributed to surgical trauma to the common duct.

The diagnosis was confirmed histologically from tissue obtained at laparotomy or by needle (Vim Silverman) biopsy of the liver in eight of the ten cases. The other two (M. G. and W. H.) were clinically typical cases, and in one of them (W. H.) an enlarged bile-stained liver was observed at three laparotomies for repair of the severely stenosed common duct.

The series has been confined to cases of biliary cirrhosis of the obstructive type, other etiologies such as parasitic infestation, etc. being excluded. No cases of essential xanthomatosis were studied.

RESULTS

Typical electrophoretic patterns are illustrated in Figure 1 and the data on the serum proteins as well as the tests of hepatic function are listed in Table I, roughly in order of increasing deviation from normal serum protein composition. The normal controls have been reported previously (4).

The electrophoretic analyses revealed diminutions of the serum albumin fractions in all cases

¹ Present address: Department of Medicine, Harvard Medical School, Boston, Mass.

TABLE I

Bromsulfalein tests on the two patients with normal serum bilirubin values, W. H. and M. F., revealed 3 per cent and 48 per cent retention respectively

even when normal by the Howe method. The gamma-globulins were elevated in eight of the ten cases. The beta-globulins were elevated in all cases, with some strikingly high values, a finding which will be further discussed. Significant increases of the alpha-one- and alpha-two-globulins occurred less frequently.

As shown in Table I, hypercholesterolemia with decreased cholesterol esters was observed although not a constant finding. Several unusually high alkaline phosphatase activities occurred, and all but two values were above normal. Cephalin cholesterol flocculation and thymol turbidity tests were positive in all but four and two instances respectively.

On the basis of their clinical status at the time of the study, the cases fell into three groups which bore some relationship to the electrophoretic data.

In the first group of two cases (W. H. and M. F.) the pathologic process was apparently quiescent and the serum bilirubin values were normal. W. H. had been entirely asymptomatic for five

months with normal tests of hepatic function including bromsulfalein retention of 3 per cent; the electrophoretic analysis showed slightly reduced albumin, elevated beta-globulin, and normal gamma-globulin. M. F. with minimal symptoms (pruritus, fatigability) for 11 months had a high alkaline phosphatase (35.1 units) and bromsulfalein retention of 48 per cent, despite normal serum bilirubin; the electrophoretic analysis revealed moderately diminished albumin and elevated beta- and gamma-globulins.

The second group of five patients (T. O., M. G., C. M., F. F., and K. V.) had active ascending cholangitis at the time of the study with varying degrees of elevation of the serum bilirubin. The electrophoretic patterns showed greater deviation from the normal than the quiescent group with, however, considerable variation. The albumin values of all but one (M. G.) were below 3 grams per cent. T. O. exhibited a strikingly high beta-globulin peak without gamma-globulin increase. M. G. and K. V. showed increased beta- and

gamma-globulins. C. M. and F. F. had some elevation of all the globulin fractions, the former with high gamma-globulin, the latter with high beta-globulin.

The third group of three patients (M. E., L. S., and L. H.) exhibited secondary xanthomatosis (palmar and palpebral) after long histories of obstructive jaundice. M. E. was studied three years after the onset of episodes of chills, fever and jaundice, and five months after cholecystectomy which had been followed by decline of the serum bilirubin to a value only slightly above the normal range. The electrophoretic analysis showed marked abnormality with diminished albumin and elevated beta- and gamma-globulins, but the pattern was far less striking than those of L. S. and L. H., the most bizarre in the series. These patients had almost complete occlusion of the common duct due to stricture following cholecystectomy five years ago in each case, and attempts at

operative repair had been futile. The onset of progressive secondary xanthomatosis occurred during periods of clinical observation long after histologic diagnoses of obstructive biliary cirrhosis had been made. The electrophoretic patterns showed spectacular beta-globulin elevations. Both had marked diminutions of the albumin fractions. The beta-globulin fraction of L. S. was exceeded by the even higher gamma globulin, which was the highest in all the cases studied. The beta-globulin of L. H. was over three times the normal in grams per cent and exceeded each of the other fractions of the serum.

Changes of electrophoretic patterns during the course of the disease were followed in three illustrative cases (K. V., L. S., and L. H.). All were given a high protein, high carbohydrate and high caloric diet containing 120 to 150 grams of protein, 350 to 450 grams of carbohydrate, a total of 3,000 to 3,500 calories, supplemented by 4 to

ELECTROPHORETIC PATTERNS OF SERUM PROTEINS IN BILIARY CIRRHOSIS

COURSE OF BILIARY CIRRHOSIS

K.V. - Cholecystectomy with rubber abdominal drain three months previously followed by intense jaundice and ascending cholangitis. Insertion of T-tube into slightly dilated common duct. Subsidence of jaundice and all symptoms. Alteration of electrophoretic pattern in the direction of normal by Day 59; little change thereafter.

L.S. - Irreparable stricture of common duct after cholecystectomy five years ago. Progressive development of secondary xanthomatosis. No significant change in electrophoretic pattern.

L.H. - Irreparable stricture of common duct after cholecystectomy five years ago. Progressive development of secondary xanthomatosis. Little change in electrophoretic pattern.

Beta-globulin peak reduced to approximately one third of original area.

FIG. 3

6 grams of choline chloride daily. During periods of acute ascending cholangitis sulfadiazine and/or penicillin was administered.

The electrophoretic patterns and data of these three patients are shown in Figure 2 and Table II.

K. V. had had a cholecystectomy three months previously with a rubber abdominal drain left in place, followed by intense jaundice and ascending cholangitis. After laparotomy with insertion of a T-tube into the slightly dilated common duct (ten days prior to *Day 0*) the jaundice and all symptoms subsided. The serial electrophoretic patterns showed evolution in the direction of normal with definite rise of the diminished albumin fraction

and some decline of the elevated beta- and gamma-globulins. The most pronounced change had occurred by *Day 59*, the pattern showing only minor alteration thereafter. During the period of study there was also change of the tests of hepatic function toward normal.

L. S. and L. H. with irreversible obstructive jaundice (severe stricture of the common duct) and secondary xanthomatosis manifested no fundamental change in clinical status during observation, although recurring episodes of acute ascending cholangitis with chills and fever were prevented by sulfadiazine (2 to 6 grams daily). The electrophoretic pattern of L. S. showed no

significant change after 49 days. After 147 days, L. H. exhibited some albumin rise and decline of the elevated gamma-globulin, while the pattern retained the same bizarre general configuration with the striking beta-globulin peak.

In contrast with these findings, portal cirrhosis has not shown marked elevation of the beta-globulin fraction as a constant or conspicuous feature. Comparison of the electrophoretic patterns of deeply jaundiced cases of biliary and portal cirrhosis is illustrated in Figure 3 where the difference between the beta-globulin peaks is striking.

Ether extraction of the serum of the case of biliary cirrhosis resulted in pronounced reduction of the beta-globulin peak to approximately one-third its original area, the conspicuous beta-globulin disturbance (spike) of the descending pattern being likewise markedly diminished. This experiment indicates the important contribution of lipo-protein to the high beta-globulin.

DISCUSSION

The ten cases of biliary cirrhosis had diminished albumin values in all instances, even when normal by the Howe method. The gamma-globulins were elevated in eight of the ten cases. The most characteristic and conspicuous feature, however, was elevation of the beta-globulins, observed in all cases and reaching spectacular levels in two cases with secondary xanthomatosis (L. S. and L. H.). These two cases with almost complete occlusion of the common duct due to post-operative stricture of five years' duration exhibited the most abnormal electrophoretic patterns of the series, one of them (L. H.) showing a beta-globulin exceeding any of the other fractions. The electrophoretic pattern nearest normal occurred in a patient (W. H.) who had been entirely asymptomatic for five months and had normal tests of hepatic function. This pattern revealed slightly diminished albumin, elevated beta-globulin and normal gamma-globulin.

The data in these cases of biliary cirrhosis contrasted with the findings in a previously reported series of cases of portal cirrhosis (4) in which elevation of the beta-globulin fraction was a less constant and less conspicuous feature, strikingly tall peaks never having been observed even when the beta-globulin was high. Moreover, in the cases of portal cirrhosis beta-globulin increases did

not occur without marked elevation of gamma-globulin.

It is of interest to compare these findings with the isolated cases previously reported. The patient with "xanthomatosis and biliary cirrhosis" of Gray and Barron (1) exhibited a serum protein composition strikingly similar to our cases with secondary xanthomatosis. The two cases of Thorn, Armstrong and Davenport (2) had major concomitant disease: in one, the biliary cirrhosis was secondary to bile duct carcinoma extensively infiltrating the liver, and in the other biliary cirrhosis was superimposed on old portal cirrhosis, the electrophoretic analyses showing slightly elevated and normal beta-globulins respectively. The patients evidently do not bear close comparison with the present series. A single case listed among the data of Cohen and Thompson (3) had only slight elevation of the beta-globulin but a very high gamma-globulin.

The experiment showing reduction of the greatly increased beta-globulin peak to approximately one-third its original area by ether extraction was interpreted as demonstrating the important contribution of lipo-protein to this pathologically elevated fraction. The same phenomenon has been observed by Longworth and colleagues in sera of patients with nephrosis (9) and obstructive jaundice (10), the one difference being that the descending beta-globulin disturbance (spike) was essentially unchanged, whereas in the present experiment it was markedly diminished after ether extraction. Zeldis, Alling and co-workers (11) reported somewhat similar results but with complete abolition of the beta-globulin disturbance employing an alcohol-ether extraction that probably caused partial denaturation of the proteins. These findings were obtained in patients with nephrosis, "obstructive jaundice with cholangitis," and other diseases. Unpublished work by Lever (12) corroborates and extends the present findings with cold ether extraction.

Longworth (9) has discussed the distinction between the lipids presumably present as suspended globules coated with beta-globulin, notably in lipemic (milky) sera which can be clarified by high speed centrifugation, and on the other hand the lipo-proteins in clear solution, which in pathologic sera (such as the present series) may be extracted by cold ether with reduction of the

abnormally high beta-globulin peak. It should be noted that the alpha- and beta-lipo-proteins of normal sera have the solubility properties of proteins (13, 14) and are not ether-extractable to any extent (9, 14). The present elevated beta-lipo-protein may differ essentially from the normal. An alternative suggestion is the possible effect of bile salts in the serum on the stability of the lipo-protein complex (15, 16).

Kunkel and Ahrens (17, 18) have emphasized the role of the phospholipid content of the lipo-proteins. The phospholipids were found to be relatively low in the lipemic (milky) sera of patients with nephrosis, but high in the transparent high-lipid sera of patients with biliary cirrhosis. The clarity of the high-lipid sera in biliary cirrhosis was attributed to the hydrophilic nature of the phospholipids by virtue of their water-soluble side chains.

Whether the elevated lipo-protein observed electrophoretically as a high beta-globulin peak is merely a phenomenon of biliary regurgitation or whether it represents some derangement of hepatic metabolism remains to be determined. The patterns with high beta-globulin peaks reported by Longworth (10) and Zeldis and Alling (11) in "obstructive jaundice" tend to support the former view, but further knowledge of hepatic function in these cases would be needed. Gray and Barron (1) emphasized that jaundice *per se* has no influence on the electrophoretic pattern and presented five jaundiced cases of common duct stone, four of which exhibited normal serum proteins. The remaining case had an elevated beta-globulin fraction, but laparotomy biopsy of the liver showed marked histologic evidence of parenchymal damage. Conversely, in the present series, two cases (W. H. and M. F. with apparently quiescent pathologic processes) showed elevated beta-globulins in the presence of normal serum bilirubin.

The observations of Balfour (19) with the aid of radioactive phosphorus together with previous data (20) suggest that in patients with high levels of plasma lipids the cause of elevated phospholipids is overproduction by the liver rather than biliary regurgitation, not only in biliary cirrhosis but also in the nephrotic syndrome and other conditions.

In the present study the serial electrophoretic analyses on sera from a patient without serious

mechanical obstruction showed alteration of the serum proteins in the direction of normal coinciding with clinical improvement, as has been observed previously in patients with portal cirrhosis under medical management (21). On the other hand, as expected, two patients with irreparable stricture of the common duct showed little change in electrophoretic pattern during the period of observation.

SUMMARY

1. Electrophoretic analyses of the serum proteins of ten cases of biliary cirrhosis of the obstructive type revealed deviations from the normal composition in all.
2. The albumin fractions were diminished in all cases and the gamma-globulins were elevated in eight of the ten cases.
3. Elevated beta-globulins were found in all cases and were sometimes strikingly increased.
4. The elevation of beta-globulins was attributed to increased lipo-protein.
5. The abnormalities of the serum proteins were greatest in two cases with irreparable post-operative stricture of the common duct and secondary xanthomatosis, and were minimal in a case without clinical symptoms at the time of study.

ACKNOWLEDGMENTS

The authors wish to express their gratitude to Dr. E. S. Guzman Barron for making available the electrophoresis apparatus used in this study, and also their indebtedness to Robert S. Levine for his invaluable technical assistance with the tests of hepatic function.

ELECTROPHORETIC STUDIES OF THE SERUM PROTEINS IN VIRUS HEPATITIS

By WILLIAM E. RICKETTS AND KENNETH STERLING¹

(From the Frank Billings Medical Clinic, Department of Medicine, The University of Chicago, Chicago, Ill.)

(Received for publication June 20, 1949)

The abnormal electrophoretic patterns of the serum proteins in the acute stage of virus hepatitis were first described by Gray and Barron in 1943 (1) and have since been confirmed by several investigators (2-5). In the last few years there has been considerable interest (6-13) in cases of hepatitis progressing to chronic liver disease, or developing post-necrotic cirrhosis. Except for the study by Martin (4), however, little information has been presented on the serum proteins after the acute stage of the disease.

The present investigation was undertaken to observe the alterations of the serum proteins during the course of virus hepatitis, including its later stages.

METHODS

Electrophoretic runs were performed with standard apparatus and technique, the experimental details having been given in an earlier report (14). The tests of hepatic function were performed by the usual methods as previously described (14), alkaline phosphatase being reported in Bodansky units. In our experience (15), the thymol turbidity test with buffer pH 7.55 has not infrequently given values of 4 or 5 units in normal individuals.

CASE MATERIAL

Ten volunteer subjects with normal tests of hepatic function served as controls, the data having been previously reported (14).

Twenty-one clinically typical cases of hepatitis were studied. Histologic verification of parenchymal involvement compatible with virus hepatitis was obtained in 14 cases, the tissue having been secured by one or more Vim Silverman needle biopsies or at laparotomy, and in two cases (E. H. and K. H.) at autopsy. On the basis of history the cases were considered to be infectious hepatitis with exception of two (T. H. and K. H.) regarded as homologous serum hepatitis, having received blood and plasma within 60 to 90 days prior to onset.

For the purposes of study, the material was divided into the following three groups:

Group I—Acute phase, ten patients.

Group II—Course of the disease, with serial electrophoretic studies on five patients over periods of 69 to 396 days.

Group III—Late follow-up studies, with single electrophoretic analyses on sera from 11 patients, ten to 36 months after the acute phase.

Serial needle biopsies and repeated tests of hepatic function were performed during the course of observation, as described below.

In addition to bed rest during the acute stage, the medical management included a high protein, high carbohydrate, high caloric diet containing 120 to 150 grams of protein, 350 to 450 grams of carbohydrate, a total of 3,000 to 3,500 calories, supplemented in most instances by 4 to 6 grams of choline chloride daily.

RESULTS

Group I—Acute phase

In all of the ten cases studied during the acute phase histologic examination of liver tissue was obtained, in two instances (E. H. and K. H.) at autopsy. Two of the ten cases (T. H. and K. H.) were regarded as homologous serum hepatitis, and the rest as infectious hepatitis.

Typical electrophoretic patterns are illustrated in Figure 1, and the data including tests of hepatic function are given in Table I, the cases being listed in order of increasing severity of the disease as judged by the overall clinical picture.

It will be readily observed that diminution of the albumin fraction occurred in all instances even when not evident by the Howe method. Elevation of the gamma-globulin fraction was usually but not invariably present (seven of the ten cases). G. A., J. E., and S. E. exhibited normal gamma-globulins, while H. S. had elevation of the relative proportion (*i.e.*, per cent) but not the absolute value (*i.e.*, grams per cent) of gamma-globulin. Elevated beta-globulins occurred in seven of the ten cases.

The first five cases (C. G., T. J., G. A., J. E., and S. E.) had mild hepatitis with slight to

¹ Present address: Department of Medicine, Harvard Medical School, Boston, Mass.

moderately intense jaundice. C. G. showed elevated alpha-2-, beta-, and gamma-globulins, with almost normal thymol turbidity and negative cephalin cholesterol flocculation test. T. J. exhibited elevation of all the globulins, with both thymol turbidity and cephalin cholesterol flocculation tests within normal limits. G. A., J. E. (Figure 3), and S. E. had normal gamma-globulins, the first two with elevated beta-globulins (and positive thymol turbidity and cephalin cholesterol flocculation tests), and the latter with elevated alpha-2-globulin and positive thymol turbidity test.

The last five cases (H. S., T. H., A. E., E. H., and K. H.) had severe acute hepatitis. Four of these were women after the menopause (H. S., A. E., E. H., and K. H.) and one (T. H.) was a 72 year old male with diffuse arteriosclerosis and hypertension. Three cases recovered clinically from the hepatitis and had no further symptoms

referable to liver disease (H. S., T. H., and A. E.), and two died of parenchymal liver failure with intense jaundice, edema, ascites, and hemorrhagic phenomena (E. H. and K. H.). The electrophoretic albumin values in this group were all below 3 grams per cent. H. S. (Figure 2) had only relative but not absolute increase of the beta- and gamma-globulins, while the others all showed pronounced relative and absolute gamma-globulin elevations. A. E. (Figure 4) and K. H. had elevated beta- as well as gamma-globulins. A high alpha-1-globulin occurred in T. H. The abnormalities of the serum proteins in these five cases of severe virus hepatitis were in general considerably more pronounced than in the five with clinically milder disease.

Group II—Course of the disease

The five cases with follow-up studies showed evolution of the electrophoretic patterns toward

ELECTROPHORETIC PATTERNS OF SERUM PROTEINS IN ACUTE VIRUS HEPATITIS

FIG. 1

The albumin peaks are indicated by "A," and the globulins by their respective Greek letter prefixes. The unlabelled peaks are the stationary anomalous boundaries due to gradients of buffer salt.

normal, but differed markedly in both the rate and extent of reversion toward normal. The changes are illustrated in Figures 2-4, and the data including tests of hepatic function are listed in Table II. The initial studies (*Day 0*) were performed during the acute phase, usually one or two weeks after the onset of the illness.

C. G., a 15 year old male, had mild acute hepatitis with slight jaundice, negative cephalin cholesterol flocculation and almost normal thymol turbidity test. A needle biopsy disclosed histologic changes compatible with virus hepatitis. The initial electrophoretic analysis (Figure 2) revealed somewhat diminished albumin despite normal Howe albumin value, and slightly elevated beta- and gamma-globulins. The jaundice subsided in two weeks; the patient became asymptomatic and remained so. The tests of hepatic function reverted to normal and the electrophoretic pattern on *Day 156* was within normal limits. A follow-up needle biopsy of the liver disclosed normal parenchyma with normal lobular architecture and minimal focal scarring.

J. E., a 35 year old female, had relatively mild

acute hepatitis, her general condition remaining quite good despite intense jaundice and pruritus. The total serum bilirubin reached a peak of 18.4 grams per cent; urobilinogen was absent from the 24 hour urine and stool collections for ten days. Microscopic findings on the needle biopsy specimen were compatible with acute virus hepatitis. The initial electrophoretic analysis (Figure 3) revealed diminished albumin and markedly elevated beta-globulin but normal gamma-globulin in the presence of a positive cephalin cholesterol flocculation test and a high thymol turbidity. Over the course of one month the jaundice and all symptoms subsided after which the patient remained asymptomatic. By *Day 20* the electrophoretic pattern had changed considerably in the direction of normal and on *Day 69*, it was within normal limits, as were the tests of hepatic function. Follow-up needle biopsy revealed marked recovery of the parenchyma with no scarring whatever.

H. S., a 72 year old female, had moderately severe acute hepatitis with intense jaundice, the serum bilirubin values attaining levels above 30

COURSE OF VIRUS HEPATITIS

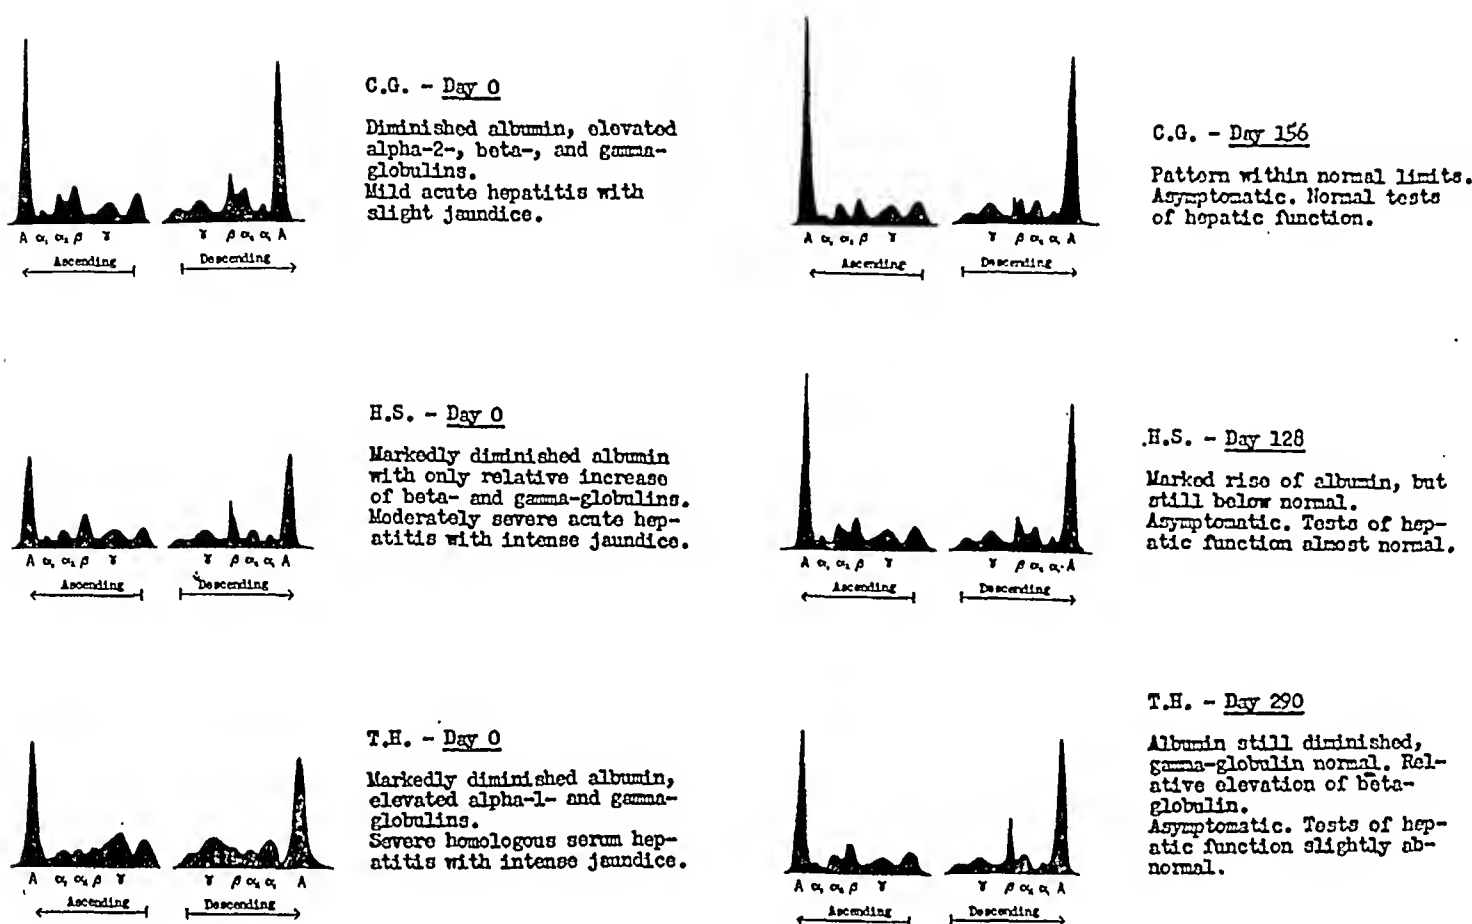

FIG. 2

mg. per cent and the tests of hepatic function revealing marked impairment. Needle biopsy disclosed acute hepatitis with some distortion of the lobular architecture. The initial electrophoretic pattern (Figure 2) was quite abnormal with very low albumin and elevation of the relative (*i.e.*, per cent) but not absolute (*i.e.*, grams per cent) values of the beta- and gamma-globulins. Within five weeks complete clinical recovery occurred with reversion of the tests of hepatic function to almost normal, and the patient remained asymptomatic. Electrophoretic analysis on *Day 128* revealed considerable change in the direction of normal with albumin rise of over 1 gram per cent, nevertheless not attaining the normal range.

T. H., a 72 year old male, had severe acute hepatitis with intense jaundice, regarded as homologous serum hepatitis since he had received blood and plasma 90 days previously at the time of a local resection of the colon for carcinoma.

Tests of hepatic function revealed marked impairment and histologic examination of the needle biopsy specimen was compatible with virus hepatitis. The initial electrophoretic study (Figure 2) showed markedly diminished albumin and elevated alpha-1- and gamma-globulins. Complete clinical recovery occurred in approximately six weeks, the tests of hepatic function remaining slightly abnormal. Electrophoretic analysis on *Day 290* revealed some change toward normal with decline of the elevated alpha-1- and gamma-globulins, but the pattern was still definitely abnormal with diminution of albumin and relative elevation of beta-globulin.

A. E., a 67 year old female with hypertensive cardio-vascular disease but without history of cardiac failure, developed unusually severe acute hepatitis with intense jaundice, the total serum bilirubin levels exceeding 30 mg. per cent. For three weeks urobilinogen was absent from the 24

COURSE OF MILD VIRUS HEPATITIS

Sera of J.E.

Diminished albumin, markedly elevated beta-globulin, normal gamma-globulin. Mild acute hepatitis with intense jaundice.

Nearly normal pattern. Minimal jaundice.

Pattern within normal limits. Asymptomatic. Tests of hepatic function almost normal.

FIG. 3

hour collections of stools and urine. The other tests of hepatic function disclosed marked impairment. Needle biopsy of the liver four weeks after the onset revealed marked inflammatory infiltration with areas of liver cell necrosis and post-necrotic scarring. The initial electrophoretic pattern (Figure 4) was quite abnormal with diminished albumin and markedly elevated beta- and gamma-globulins. After eight weeks of jaundice there was gradual complete clinical re-

covery, the patient's cardio-vascular status remaining unchanged throughout. The tests of hepatic function exhibited progressive reversion to almost normal, the thymol turbidity remaining slightly elevated even after a year had elapsed. The electrophoretic pattern on *Day 21*, by which time considerable clinical improvement had occurred, was still quite abnormal but revealed a rise of the albumin and a decline of the elevated beta- and gamma-globulins. On *Day 396*, definite

COURSE OF SEVERE VIRUS HEPATITIS WITH POST-NECROTIC CIRRHOSIS

Sera of A.E.

Markedly abnormal pattern with diminished albumin, elevated beta- and gamma-globulins. Severe acute hepatitis with extreme jaundice.

Pattern still quite abnormal, but with rise of albumin, decline of beta- and gamma-globulins. Considerable clinical improvement. Minimal jaundice.

Pattern still abnormal with diminished albumin, elevated alpha-2-, beta-, and gamma-globulins. Asymptomatic. Tests of hepatic function almost normal. Post-necrotic cirrhosis histologically.

residual abnormalities were observed with diminished albumin and elevated alpha-2-, beta-, and gamma-globulins. Follow-up needle biopsy of the liver revealed definite post-necrotic cirrhosis with distortion of the lobular architecture.

Group III—Late follow-up studies

To assess the late effects of virus hepatitis, single electrophoretic analyses were performed on sera from 11 individuals who had clinically recovered from acute hepatitis during hospital admissions 10 to 36 months previously. In all cases tests of hepatic function had been carried out at intervals. None of the patients were alcoholics or had symptoms referable to the liver or gall bladder prior to the onset of acute hepatitis. Except for C. B., none had recurrent jaundice after the initial episode.

Typical electrophoretic patterns are illustrated in Figure 5 and the data including the tests of hepatic function are listed in Table III in order of increasing deviation from normal serum protein composition.

Although most of the residual abnormalities were relatively minor, only three sera (C. B.,

C. J., and W. R.) had patterns well within the normal range. The electrophoretic albumin values (absolute) were slightly diminished in four (J. G., C. P., M. K., and M. J. S.) of the 11 cases, although this was not reflected in the Howe fractionations. The gamma-globulins were elevated in six cases (G. G., R. W., J. G., C. P., M. K., and M. J. S.) and the beta-globulins in five (M. S., B. W., G. G., R. W., and M. J. S.).

Summaries of the findings in the 11 cases follow:

C. B., a 24 year old male, had mild infectious hepatitis with intense jaundice while in military service with recurrence of jaundice two months later. He had been asymptomatic during the ensuing 28 months. The electrophoretic pattern was within normal limits. There was definite elevation of the total serum bilirubin, other tests of hepatic function being normal.

C. J., a 29 year old male, had been asymptomatic following recovery from mild acute hepatitis 32 months previously. The electrophoretic data were in the normal range. Tests of hepatic function were normal.

W. R., a 26 year old male, had recovered uneventfully from mild acute hepatitis 34 months previously and remained free of symptoms. The electrophoretic pattern was within normal limits. Tests of hepatic function were normal except for slightly elevated thymol turbidity (6.1 units). Needle biopsy revealed normal liver tissue.

LATE FOLLOW-UP STUDIES

long after clinical recovery from acute virus hepatitis

W.R. - Pattern within normal limits. Asymptomatic 3½ months after mild acute hepatitis. Almost normal tests of hepatic function. Normal liver histologically.

M.S. - Pattern normal except for elevated beta-globulin. Asymptomatic 1½ months after severe acute hepatitis. Normal tests of hepatic function.

G.G. - Elevated beta- and gamma-globulins. Asymptomatic 16 months after mild acute hepatitis. Normal tests of hepatic function.

J.G. - Slightly diminished albumin, slightly elevated gamma-globulin. Asymptomatic three years after severe acute hepatitis. Almost normal tests of hepatic function. Minimal post-necrotic scarring histologically.

M.K. - Slightly diminished albumin, elevated gamma-globulin. Asymptomatic 1½ months after severe acute hepatitis. Normal tests of hepatic function. Minimal post-necrotic scarring histologically.

M.J.S. - Diminished albumin, elevated beta- and gamma-globulins. No symptoms attributable to liver disease 29 months after severe acute hepatitis. Positive cephalin flocculation and thymol turbidity tests. Post-necrotic scarring histologically.

M. S., a 24 year old male, had severe acute hepatitis with intense jaundice 14 months previously from which he achieved complete clinical recovery. The electrophoretic pattern was normal except for elevated beta-globulin. Tests of hepatic function were normal.

B. W., a 47 year old female, had been asymptomatic following moderately severe acute hepatitis 21 months previously. Electrophoresis disclosed elevation of the beta-globulin fraction. Bromsulfalein test showed 30 per cent retention, the other tests being normal.

G. G., a 50 year old male, had recovered from mild infectious hepatitis 16 months previously and remained asymptomatic thereafter. Electrophoretic analysis revealed elevated beta- and gamma-globulins. All tests of hepatic function were normal.

R. W., a 64 year old male, had recovered uneventfully from mild acute hepatitis 12 months previously. Electrophoresis showed elevation of the beta- and gamma-globulin fractions. The tests of hepatic function were normal except for slightly elevated thymol turbidity (6.2 units).

J. G., a 58 year old male, had been asymptomatic for 36 months following recovery from severe acute hepatitis (with laparotomy biopsy). Electrophoretic analysis revealed diminished albumin and slightly elevated gamma-globulin. The total serum bilirubin was 1.2 mg. per cent, other tests of hepatic function being normal. Two consecutive needle biopsies of the liver showed minimal post-necrotic scarring.

C. P., a 55 year old female, had recovered from moderately severe acute hepatitis ten months previously and remained free of symptoms. The electrophoretic findings were diminished albumin and elevated gamma-globulin. Bromsulfalein test showed 27 per cent retention, and the cephalin cholesterol flocculation and thymol turbidity tests were positive.

M. K., a 48 year old male, had been asymptomatic for 14 months after severe acute hepatitis. Electrophoresis revealed diminished albumin and elevated gamma-globulin. Tests of hepatic function were all normal. Needle biopsy of the liver showed minimal post-necrotic scarring.

M. J. S., a 62 year old female, had severe hepatitis (with laparotomy biopsy) 29 months previously with complete clinical recovery. There had been no symptoms referable to the liver since then. The electrophoretic pattern was the most abnormal of the group, with diminished albumin and elevated beta- and gamma-globulins. The cephalin cholesterol flocculation was 4+ and thymol turbidity was 9.0 units, the highest values in the group, the other tests of hepatic function being normal. Needle biopsy of the liver revealed post-necrotic scarring with disturbed architecture.

DISCUSSION

Electrophoretic analyses of the serum proteins in virus hepatitis were first described in 1943 by Gray and Barron (1) who reported five cases with diminished albumin in all, elevated gamma-

globulin in four, and elevated beta-globulin in two. These observations have been confirmed and extended by subsequent investigations (2-5), including the present study.

The ten cases of acute virus hepatitis studied all exhibited diminished albumin values on electrophoretic analysis, even when not evident by the Howe fractionation. Elevated gamma-globulins occurred in seven of the ten cases, and elevated beta-globulins in the same number, other variations being less frequent.

Comparison of the five clinically mild with the five severe cases of acute hepatitis revealed no strict correlation between clinical severity and extent of deviation from normal serum protein composition. This is well illustrated by the case of T. J. with quite mild clinical manifestations and slight jaundice, yet considerable abnormality of the electrophoretic pattern. On the other hand, the five severe cases all had markedly abnormal patterns, with generally greater deviations from normal than the mild cases.

The changes show similarities to those observed in a previous study of portal cirrhosis (14). The cases of portal cirrhosis with clinical manifestations such as jaundice, edema, or ascites had more pronounced abnormalities, however. In such patients, moreover, beta-globulin increases without marked elevation of gamma-globulin did not occur, in contrast to the virus hepatitis cases G. A. and J. E., with beta-globulin elevations alone. The patterns in acute virus hepatitis also resembled those observed in Weil's disease (16), chronic Brucella hepatitis (17), and infectious mononucleosis (18).

The question has been raised whether these alterations are manifestations of hepatic dysfunction or of the infectious process. Somewhat similar abnormalities have been described in infectious diseases such as syphilis, tuberculosis, typhus, malaria, lymphogranuloma venereum, leprosy, kala-azar and others (19), not believed to involve the liver, or at least not accompanied by clinical hepatic insufficiency. It must, however, be noted that most of the above conditions are characterized by chronic proliferative granulomata or by widespread cellular destruction, hence are not necessarily strictly comparable with virus hepatitis. On the other hand, in lobar pneumonia there are elevations of the alpha-2-globulins

usually without significant changes in the gamma-globulins (19, 20). Although a final answer to the problem cannot be given on the basis of the present evidence, it is suggested that the hepatic involvement in virus hepatitis plays a major role in the disturbances of the serum proteins.

The current interest in the late manifestations of virus hepatitis with prolonged hepatic dysfunction or post-necrotic cirrhosis led to the follow-up studies undertaken. To our knowledge the only previous investigation with serial electrophoretic analyses of virus hepatitis sera has been that of Martin (4) in which the maximum period of observation was 64 days. Martin's data show a number of positive findings on tests of hepatic function at the end of observation, but abnormalities of the electrophoretic patterns in only two of his 11 cases.

The present data, on the contrary, demonstrate the frequent occurrence of residual abnormalities of the serum proteins even after long asymptomatic periods.

Of the five cases followed after the acute phase, two with mild acute hepatitis showed complete reversion to normal serum protein composition. The other three with more severe acute episodes exhibited residual abnormalities of the electrophoretic pattern 128, 290, and 396 days after the initial study even though the patients were asymptomatic and had almost normal tests of hepatic function.

The late follow-up studies on sera from individuals who had clinically recovered from the acute phase of virus hepatitis ten to 36 months previously revealed frequent if usually slight abnormalities of the electrophoretic pattern. Of the 11 examined, only three patterns were considered well within the normal limits. Among the group of sera there were four instances of diminished albumin values, six elevated gamma-globulin fractions, and five elevated beta-globulins. Residual abnormalities in one or more tests of hepatic function were likewise observed. No cases of virus hepatitis with chronic jaundice were encountered.

Post-necrotic scarring was demonstrated on follow-up needle biopsy of the liver in four cases (J. G., M. K., M. J. S., and A. E.). These four patients had normal bromsulfalein tests as well as prompt (1 minute) bilirubin values (21). The

electrophoretic patterns revealed definite residual abnormalities, relatively minor in J. G. and M. K., and more marked in M. J. S. and A. E.

The occurrence of positive cephalin cholesterol flocculation and thymol turbidity tests in the presence of normal values for gamma-globulin, and conversely the occurrence of abnormalities of the serum proteins without positive flocculation or turbidity tests has been pointed out in the presentation of the data above. These findings, while of interest, are not unexpected in view of the complexity of these reactions. Recent investigations (3, 5, 22-26) have shed some light on the mechanisms of these tests, such as the evidence for the role of lipo-protein of the beta-globulin fraction in the thymol turbidity test. Nevertheless, many problems of the precise interactions of the proteins remain to be clarified.

SUMMARY

1. Electrophoretic analyses of the serum proteins in ten cases of acute virus hepatitis revealed diminished albumin values in all, elevated gamma-globulins in seven of the ten, and elevated beta-globulins in the same number.
2. Cases of severe acute hepatitis showed in general more pronounced changes than milder cases, but no strict correlation existed.
3. Serial electrophoretic analyses disclosed reversion of the serum proteins to normal in two cases of acute hepatitis, but persistent abnormalities were observed in three cases despite clinical recovery.
4. Late follow-up studies on sera from 11 individuals who had clinically recovered from acute virus hepatitis ten to 36 months previously revealed residual abnormalities in the electrophoretic patterns of eight of the 11 sera.

INFLUENCE OF THE ADRENAL CORTEX ON BODY WATER DISTRIBUTION AND RENAL FUNCTION¹

BY MARIO GAUDINO² AND MARVIN F. LEVITT³

(From the Department of Physiology, New York University College of Medicine,
New York City)

(Received for publication June 16, 1949)

A relation between the adrenal cortex and the distribution of body water has been recognized since the first demonstration that adrenal insufficiency was associated with a marked degree of hemoconcentration (1, 2). The suggestion that this hemoconcentration might be attributed to a decrease in plasma volume (3, 4) was later confirmed by direct measurement (4-8), and by the circumstance that normal plasma volume was restored with adequate desoxycorticosterone therapy (6-9).

The administration of cortical extract to animals in adrenal insufficiency was followed by hemodilution and diuresis even though no water was ingested (10, 11). Swingle and his collaborators suggested that adrenalectomized animals were unable to mobilize fluids from the interstitial and cell space (10), and that the hormone effected the redistribution of fluids in the organism (12). According to Harrop (11), fluid entered cells during insufficiency and was released by therapy. The extracellular space, as judged by the volume of distribution of chloride and thiocyanate, was decreased after adrenalectomy and restored by hormone therapy (7, 8, 11, 13). Moreover, the picture of adrenal insufficiency was simulated by peritoneal dialysis, a procedure which reduces extracellular fluid volume (11, 14, 15, 16).

As a consequence of the changes noted in serum electrolyte pattern during adrenal insufficiency (1, 2, 17), attention was focused on the simultaneous electrolyte and water changes in the tissues (16, 18-23). Calculations of the tissue water compartments, based upon the assumption that chloride is limited to extracellular distribution, revealed a

shift of water from the interstitial into the intracellular space (20-23).

Marshall and Davis (24), by measuring the excretion of phenolsulfonephthalein, urea and creatinine, demonstrated a decrease in renal function following complete adrenalectomy. The subsequent use of more precise measures of renal activity confirmed the latter observation. Inulin, creatinine, urea and diodrast clearances as well as diodrast Tm were found to be reduced after adrenalectomy and restored after adequate hormone therapy (25-29).

In view of the above evidence, it seemed desirable to measure changes in all the body water compartments and to correlate them with modifications in renal function observed simultaneously in animals subject to alterations of adrenal function. Previous methods for the estimation of the extracellular space used either thiocyanate or chloride, both of which substances are now known to enter cells in a variable proportion (30-36). To overcome this objection a more accurate method (inulin space) for the determination of the extracellular volume was devised (37, 38). Coupled with the use of heavy water (D_2O) as a measure of the total body water, accurate estimates of intracellular volume were feasible. The use of radioactive sodium (Na^{24}) or potassium (K^{42}) afforded means for determining the intracellular distribution of these ions.

METHODS

Extracellular space was measured as the volume of distribution of inulin. The total inulin recovered, after the cessation of a constant intravenous equilibrating infusion, corrected for urinary delay time, and divided by the plasma concentration at the moment of the interruption of the infusion, equals the volume of distribution of inulin (38).

Total body water was determined by the space of distribution of heavy water (D_2O). A known amount of D_2O was injected intravenously and blood samples were drawn two and three hours later. The bloods were

¹ Part of these results have been published in an abstract form in *Federation Proc.*, 1949, 8, 54.

³ Emanuel Libman Fellow. Present address: The Mt. Sinai Hospital, Department of Medicine, New York City.

analyzed for D₂O concentration by the falling drop method of Keston, Rittenberg and Schoenheimer (39). Intracellular volume was calculated as the difference between the D₂O and the inulin spaces. The plasma volume was determined with T-1824 (40) and the thiocyanate space was measured by the procedure of Crandall and Anderson (30).

Inulin clearance (C_{In}), p-aminohippuric acid clearance (C_{PAH}) and maximal tubular excretory capacity for p-aminohippurate (T_{mPAH}) were determined during the equilibrating inulin infusion following the standard procedure of Smith and his co-workers (41). The chemical analyses were done with the method of Harrison (42) for inulin and of Bratton and Marshall (43) modified (41) for PAH.

Plasma sodium and potassium were measured with an internally compensated Perkin-Elmer flame photometer. The total cation in the body was determined by "in vivo" dilution of Na²⁴ or K⁴², the radioactivity of the plasma being measured with a Geiger-Müller counter on a three-hour sample for Na²⁴ and on a nine-hour sample for K⁴² (44, 45). The average intracellular cation concentration was calculated according to a method described previously (44, 45). The plasma NPN was determined by the Folin and Wu method (46), and plasma specific gravity with the copper sulphate method (47). The blood pressure was measured directly in the femoral artery (Tycos gauge) and the hematocrit determined by the usual procedure.

Observations were made on normal, trained, unanes-

FIG. 1. ACTION OF DCA IN A NORMAL DOG

The results of Dog 3 reported in Table I are expressed as percentile deviations from the control values in relation to time.

thetized female dogs in a 24-hour fasting state, and an identical procedure for clearances and space determinations was followed in each experiment. At least three complete control experiments of this type were performed, and then the animals were divided into three groups: one was treated with desoxycorticosterone acetate (DCA),⁴ the second with adrenal cortical extract⁵ and the third was adrenalectomized and maintained exclusively on DCA, studies being made before and after withdrawal of DCA. In the first two groups, the dogs were followed until the physiological variables had returned to control values.

RESULTS

Action of desoxycorticosterone acetate: Three normal dogs were injected intramuscularly with 20 or 30 mg. of desoxycorticosterone acetate (DCA) in oil daily for three weeks, four to six series of observations being made during that period (Table I, Figure 1). The most pronounced and earliest response noted was a change in the distribution of body water. Whereas the total body water remained nearly constant, falling about

10 per cent from the control value, the intracellular volume progressively decreased while the extracellular volume expanded. This fluid shift was apparent on the second day of treatment (Dog 3, Figure 1) and attained its maximum on the 10th or 11th day when the intracellular volume in Dogs 1, 2 and 3 diminished 33, 34 and 43 per cent, respectively, and the extracellular space increased 53, 46 and 40 per cent.

The volume of distribution of thiocyanate qualitatively tended to follow the extracellular space, as measured by inulin, but no constant relation was maintained between them. Plasma volume in general did not change significantly, despite the large transfers of water in the other compartments; Dog 2, however, showed an irregular increment of about 30 per cent from control values with no definite relation to the changes in extracellular fluid.

At the same time that the redistribution of body water occurred, there was a progressive increase in filtration rate of 37, 40 and 53 per cent in Dogs 1, 2, and 3, respectively, an increase which was fairly well correlated with the expansion of the extracellular space, the peak changes coinciding in time. The renal plasma flow also increased, but to a lesser extent, with a consequent increase in the filtration fraction. Tm_{PAH} , on the contrary, was reduced to 26, 74 and 32 per cent, without any obvious correlation with the other changes.

The serum potassium fell to a little above half of its control value, but no changes were detected in plasma sodium. Plasma specific gravity and the hematocrit both declined slightly during the

		mEq.	mEq.	cc.	mEq./liter
Control		962	948	8,750	108
Treatment with 30 mg. DCA daily	11	845	834	5,460	152

period of treatment, while no significant variations were observed in the mean blood pressure or in the plasma non-protein nitrogen concentration.

In each of the dogs the modifications noticed as a consequence of the treatment augmented progressively, reaching a maximum approximately on the 11th day, and then tended to return to normal despite the continuation of the injection of DCA and despite an increase in dosage in Dog 1. The

plasma potassium concentration was the sole exception in that it reverted only partially after having reached its lowest level. Two to six weeks after the treatment had been discontinued, all the animals had returned to normal.

The changes in total body sodium were studied in Dog 1 (Table II). During treatment with DCA the total body sodium increased by 30 per cent over the control value, with a simultaneous increase in the average intracellular concentration of this ion.

Total potassium was measured in Dog 3 (Table III) and at the height of the response to the treatment, when the serum potassium was 2 mEq./liter, it had decreased 12 per cent; since the intracellular water had decreased by 39 per cent, intracellular concentration had increased significantly.

Action of adrenal cortical extract: Three normal dogs (Dogs 4, 5 and 6) were treated daily

FIG. 2. ACTION OF THE ADRENAL CORTICAL EXTRACT IN A NORMAL DOG

The results of Dog 5 taken from Table IV are expressed as percentile deviations from the control values in relation to time.

with 15 cc. of Upjohn's beef adrenal cortical extract for 13 days, and two or three observations were made during that period (Table IV, Figure 2).

The changes obtained differed markedly from those produced by DCA and involved body water distribution without alterations in renal function or plasma electrolyte levels. Cortical extract caused an increase in the intracellular fluid volume and in total body water, with little or no change in the extracellular space. The enlargement of the intracellular space amounted to 40, 39 and 25 per cent of control values and was apparent on the third day of the treatment (Figure 2). The extracellular space did not change in Dogs 4 and 5 and increased moderately (23 per cent) in Dog 6. Thiocyanate volume followed these variations in a somewhat irregular manner. Plasma volume did not show any significant change.

There was no marked change in C_{in} or C_{PAH} , although the former again showed a fair correlation with the extracellular volume. Tm_{PAH} in-

creased almost 74 per cent in Dog 4 and in the other two animals first decreased and subsequently rose above control values.

Plasma sodium, potassium and non-protein nitrogen concentration did not vary to any significant extent, nor did the hematocrit or the mean blood pressure. No determinations of the total cation in the body were made.

The modifications in the intracellular space induced by cortical extract also tended to disappear under prolonged treatment.

Effect of total adrenalectomy: Two normal dogs (Figures 3 and 4, and Table V) were completely adrenalectomized in two stages and maintained with 10 and 15 mg. of DCA daily (Dogs 7 and 8).⁶ While still under treatment and showing no signs of adrenal insufficiency, an experiment was performed six days after complete adrenalectomy in Dog 8 and after 21 days in Dog 7. In both animals the changes from preoperative values were similar to those observed in normal dogs treated with DCA, i.e., intracellular water was reduced

⁶ The dogs were maintained on their usual diet. No sodium chloride was added.

FIG. 3. EFFECT OF TOTAL ADRENALECTOMY ON DOG 7

The results of Table V are expressed as percentile deviations from the control values in relation to time.
